Running title: ESRP2 methylation in Wilms tumour.

Keywords: Wilms tumour, Epigenetics, DNA methylation, ESRP2, MET

Abbreviations: ANOVA, analysis of variance; Aza, 5-aza-2’-deoxycytidine; BCH, Bristol Children’s Hospital; DMEM, Dulbecco’s modified Eagle’s medium; Dox, doxycycline; FBS, fetal bovine serum; FK, fetal kidney; MCIP, methyl CpG immunoprecipitation; MET, mesenchymal-epithelial transition; NK, normal kidney; NR, nephrogenic rest; NT, normal tissue; QPCR, quantitative real-time PCR; RMH, Royal Marsden Hospital; RNA-seq, RNA sequencing; WT, Wilms tumour.
ABSTRACT

Wilms tumour (WT), an embryonal kidney cancer, has been extensively characterised for genetic and epigenetic alterations, but a proportion of WTs still lack identifiable abnormalities. To uncover DNA methylation changes critical for WT pathogenesis, we compared the epigenome of fetal kidney with two WT cell lines, filtering our results to remove common cancer-associated epigenetic changes, and to enrich for genes involved in early kidney development. This identified four hypermethylated genes, of which ESRP2 (epithelial splicing regulatory protein 2) was the most promising for further study. ESRP2 was commonly repressed by DNA methylation in WT, and this occurred early in WT development (in nephrogenic rests). ESRP2 expression was reactivated by DNA methyltransferase inhibition in WT cell lines. When ESRP2 was overexpressed in WT cell lines, it inhibited cellular proliferation in vitro, and in vivo it suppressed tumour growth of orthotopic xenografts in nude mice. RNA-seq of the ESRP2-expressing WT cell lines identified several novel splicing targets. We propose a model in which epigenetic inactivation of ESRP2 disrupts the mesenchymal to epithelial transition in early kidney development to generate WT.
1 INTRODUCTION

Wilms tumour (WT; nephroblastoma) is an embryonal kidney cancer [1, 2], which originates from fetal kidney (FK), due to the failure of the mesenchymal to epithelial transition (MET) that the metanephric blastema undergoes during early nephrogenesis. Premalignant lesions (nephrogenic rests; NRs) are often found as microscopic lesions in the normal kidney (NK) adjacent to WTs [3]. It is hypothesised that genetic and epigenetic defects occur during renal development that block MET, leading to the formation of NRs, some of which progress to WT [1-3].

The molecular events underlying WT pathogenesis involve an array of genetic and epigenetic defects [2]. The earliest genetic mutations in WT were found in the WT1 gene, which plays a critical role in regulating MET during nephrogenesis [2]. The Wnt pathway is also vital in renal development [2], and mutations in Wnt pathway components including CTNNB1 [4, 5] and WTX (AMER1) [6] have also been found in WT. Recent genome-wide sequencing studies have identified mutations in microRNA-processing genes, such as DROSHA, DICER and DGCR8, and mutations in other renal developmental regulators, including SIX1, SIX2 and SALL1 [7-12]. Most of these events show no strong association with clinical outcome, but TP53 mutations are found in the rare anaplastic variant of WT, which has a much poorer prognosis than other subtypes [13].

Epigenetic alterations are also common in WT, especially at the 11p15 locus, where the frequent loss of imprinting of the fetal growth factor gene IGF2 is associated with DNA hypermethylation at H19 [14]. Other epigenetic alterations in WT include loss of imprinting at 11p13 involving imprinted WT1 transcripts [14, 15], global hypomethylation [16], DNA hypermethylation at individual tumour suppressor genes such as RASSF1A [16-18], and long-range epigenetic silencing of the PCDHG@ gene clusters [19].

Despite the identification of many loci with genetic and/or epigenetic lesions in WT, a proportion of WTs still lack identifiable driver defects, implying that additional novel genes are involved in WT pathogenesis [7]. We previously used genome-wide DNA methylation analysis to identify novel epigenetic lesions in WT [19], and here we report further studies comparing WT cell lines to fetal kidney. We have identified novel differentially methylated genes, one of which is the alternative splicing regulator ESRP2 (epithelial splicing regulatory protein 2). ESRP2 is known to be important in epithelial to mesenchymal transitions and MET [20], suggesting that epigenetic deregulation of MET may be an important factor in WT development. We show that ESRP2 is frequently silenced by DNA hypermethylation in WT, and that it acts as a tumour suppressor.
gene, regulating alternative splicing in novel genes, some of which affect pathways known to be
important in kidney development.

2 MATERIALS AND METHODS

2.1 Ethical statement

WT samples were from Bristol Children’s hospital (BCH), or from collaborators at the Royal
Marsden Hospital (RMH), as part of a UK collaboration. Samples were obtained with informed
written consent (from parent and/or legal guardian for children less than 18 years old) and with
appropriate ethical approval (E5797, Southwest – Central Bristol Research Ethics Committee
(UK)). All methods were performed in accordance the relevant regulations specified in the UK
Human Tissue Act 2004. The study methodologies conformed to the standards set by the
Declaration of Helsinki. All animal experiments and procedures were approved by the UK Home
Office in accordance with the Animals (Scientific Procedures) Act 1986. Mice were maintained at
the Biological Services Unit, University of Exeter, UK. Housing and handling of mice have been
done according to the UK Home Office Code of Practice:
/388895/COPAnimalsFullPrint.pdf.
2.2 Cell lines

WT cell lines Wit49 (a kind gift from Professor Herman Yeger, University of Toronto) [21] and 17.94 (established in our own lab; available from DSMZ (German Collection of Microorganisms and Cell Cultures), https://www.dsmz.de/dsmz) [22] were grown in Dulbecco’s modified Eagle’s medium (DMEM) with 10% fetal bovine serum (FBS), 100 U/ml penicillin, 0.1 mg/ml streptomycin and 2mM L-glutamine, at 37°C in 5% CO₂. WT cell line identity was confirmed by short tandem repeat analysis (supplementary figure S1).

The V200 and E200L cells lines were derived by transfecting Wit49 cells with the inducible expression vector pBIG2r [23], either empty (V200) or containing an ESRP2 cDNA insert (E200L). ESRP2 cDNA was amplified by PCR from IMAGE clone 4810948, using a forward primer containing a BamHI site and a reverse primer containing an EcoRV site plus a FLAG tag (supplementary table S1), then ligated into BamHI/EcoRV-digested pBIG2r (supplementary figure S2A). Transfected cells were selected and maintained in 50 µg/ml hygromycin B (Santa Cruz Biotechnology). Only the ESRP2-transfected Wit49 cells (E200L) expressed vector-derived ESRP2 RNA (supplementary figure S2B). ESRP2 expression was induced with 2-5 µg/ml doxycycline (Dox, Sigma), with maximum ESRP2 protein expression at 72 to 96 hrs post-induction (supplementary figure S2C).

2.3 Transient transfection

WT cell lines Wit49 and 17.94 were seeded into 6 well plates (2x10⁵ cells/well) and transfected with 1µg plasmid expressing FLAG-tagged Esr1 or Esr2, or empty vector (pIBX-C-FF-B-Esrp1/2 [24]), using FuGENE 6 (Promega), according to the manufacturer’s instructions. Transfected cells were selected with 2.5 µg/ml blasticidin (Sigma) after three days, and after five days, adherent cells were trypsinised and counted.
2.4 Cell growth assays

For mass culture assays, cells were seeded into 6 well plates \((1 \times 10^6 \text{ cells/well})\) and treated with 2 \(\mu\text{g/ml}\) doxycycline or DMSO vehicle control, with medium changes every 3 days. Cells were trypsinised and counted using a Countess cell counter and trypan blue stain to exclude dead cells.

For colony assays, cells were seeded into 6 well plates \((2 \times 10^5 \text{ cells/well})\) and treated with 2 \(\mu\text{g/ml}\) doxycycline or DMSO vehicle control. Medium was changed every 3 days, then at 14 days cells were fixed, stained with methylene blue and colonies counted manually.

To monitor proliferation in real time, cells were seeded in 24-well plates \((5 \times 10^3 \text{ cells/well})\) and images were taken in four different fields per well every two hours (IncuCyte ZOOM live cell imaging system; Essen BioScience) and phase confluence was calculated as a surrogate for growth.

2.5 Transwell assay

Cells were pre-treated for 4 days with 2 \(\mu\text{g/ml}\) doxycycline or control media, then seeded into transwell inserts \((2 \times 10^5 \text{ cells/insert in FBS-free DMEM}; 8 \mu\text{m pore, PET membrane; Falcon, 353093})\) in a 6-well plate. Wells were filled with 1.7 ml 10% FBS in DMEM to produce a chemotactic gradient. After 24 hours, inserts were washed and cells on underside of membrane were fixed and stained with crystal violet and counted manually using light microscopy.

2.6 Scratch assay

Cells were seeded into 24 well plates \((7.5 \times 10^5 \text{ cells/well})\) and treated with 2 \(\mu\text{g/ml}\) doxycycline or DMSO vehicle control, prior to a scratch being performed manually in the centre of each well. Wells were washed with PBS to remove dead cells, control/doxycycline media replaced, and wells were analysed at 24 and 48 hours via widefield microscopy, using Image J software to determine percentage wound closure.

2.7 Cell Trace Violet (CTV) proliferation assay
1x10^6 cells were incubated for 20 min at 37°C in the dark in 1 ml of diluted CTV stain (ThermoFisher; C34571; prepared according to manufacturer’s instructions), then staining was quenched using 10% FBS in DMEM and cells were seeded into T12.5 flasks. Controls were made by fixing 3x10^5 stained cells in 1% paraformaldehyde and stored at 4°C in the dark. Seeded cells in T12.5 flasks were treated for 6 days with 2 µg/ml doxycycline or control media and intensity of CTV staining was analysed using a Novocyt flow cytometer and FlowJo software.

2.8 5-Aza-2’-deoxycytidine treatment

Cells were incubated in medium containing 2µM 5-aza-2’-deoxycytidine (Aza; Sigma) or drug solvent (DMSO) for up to 6 days, with a medium change every two days.

2.9 Xenografting into nude mice

V200 and E200L cells were transduced with lentivirus expressing firefly luciferase (Amsbio LVP326) and transduced cells were selected with blasticidin, according to the manufacturer’s protocol. For orthotopic kidney implantation, male nude mice (two months old; Charles River) were anaesthetised using isoflurane, an incision was performed in the left flank of the mice, the kidney was exteriorised and 3x10^6 cells were injected. Mice were imaged twice weekly (Xenogen IVIS), following intraperitoneal injection with luciferin. When a bioluminescent signal above background was detected (demonstrating the establishment of tumour growth) mice were injected intraperitoneally with doxycycline three times/week (50 mg/kg in 5% glucose). Mice were culled either when tumours grew to the maximum allowed size (10mm in diameter, according to the animal licence), or after two months of imaging. The sample size was determined by power calculations using existing data from similar experiments performed routinely in Dr Oltean’s lab. More specifically, the sample size was obtained to be able to see a significant difference (p>0.05) for tumour growth with a power value of 0.80 (>80%). We have used statistical principles and formulas available on the following websites: www.nc3rs.org.uk; http://www.statisticalsolutions.net/pss_calc.php. We have not done randomization in the animal experiments and there was no blinding of the investigator.
2.10 DNA extraction and methyl CpG immunoprecipitation (MCIP)

DNA was extracted from WT cell lines with a DNeasy kit (Qiagen). Human fetal kidney DNA was obtained from BioChain. MCIP was performed as described previously [25] by co-hybridising methylation-enriched DNA fractions with input DNA on to a custom microarray (Nimblegen), based on design 2006-04-28_HG18_Refseq_Promoter (see GEO entry for further details). Statistical analyses by ChIPMonk software (https://www.bioinformatics.babraham.ac.uk/projects/chipmonk/), used windowed T-tests to identify differentially methylated genes (supplementary table S2). MCIP data are accessible through GEO Series accession number GSE153047: https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE153047.

2.11 Pyrosequencing

DNA was purified by phenol-chloroform extraction, bisulfite converted (EZ DNA Methylation Gold kit; Zymo Research), amplified using a Pyromark PCR kit (Qiagen) and pyrosequenced on a PyroMark Q96 instrument (Qiagen), using primers listed in supplementary table S3.
2.12 RNA extraction, cDNA synthesis and RT-PCR

Total RNA was extracted using TriReagent (Sigma) and DNase treated with TURBO DNA-free (Ambion). Human fetal kidney RNA was obtained from BioChain. cDNA was synthesized using the Superscript IV RT-PCR system (Invitrogen). Gene-specific primers (supplementary table S1) were used for end-point PCR (HotStarTaq Plus DNA Polymerase; Qiagen), to detect inclusion or exclusion of alternative exons, after electrophoresis on agarose gels (1.5%). Quantitative real-time PCR (QPCR) using gene-specific primers (supplementary table S1) was performed using QuantiNova SYBR Green mix (Qiagen) on an MX3000P real-time PCR machine (Stratagene), normalising the amount of target gene to the endogenous level of TBP. Human universal RNA (Agilent) was used as a reference to standardise results between QPCR batches.

2.13 Protein extraction and Western Blotting

Cells were washed with ice-cold PBS and lysed in cell lysis buffer (Cell Signaling), with complete mini-inhibitors (Roche) for 10 min on ice, and then sonicated for 5 min (Diagenode, Bioruptor). 25 µg proteins were separated on SDS-polyacrylamide gels and analysed by Western blotting. Primary antibodies were against ESRP2 (rabbit, Abcam ab155227), FLAG (mouse, Sigma F3165) and β-ACTIN (rabbit, Abcam AB8227), followed by secondary HRP-labelled anti-rabbit IgG (Sigma A6154) or anti- mouse IgG (Sigma A9044). Chemiluminescence detection was with Lumiglo (KPL).

2.14 Immunofluorescence

Cells were grown on sterile glass slides, fixed for 30 min at room temperature in 1% paraformaldehyde in PBS, permeabilised for 10 min in 0.5% Triton X-100 in PBS and finally rinsed in 50mM glycine in PBS. Fixed cells were stained using a primary antibody against FLAG (mouse, Sigma F3165) and secondary antibody against mouse IgG (Alexa Fluor 488-labelled; Invitrogen) to detect transfected ESRP2, together with Alexa Fluor 594-labelled phalloidin (Invitrogen) to detect actin. Antibodies were diluted in PBS +1% bovine serum albumin, containing 0.1 µg/ml DAPI to image nuclei. Slides were mounted in Fluoroshield (Sigma) and examined with a confocal microscope, acquiring eight images at 1µm spacing/field. Maximum intensity projections were merged using Image J software (http://imagej.nih.gov/ij/).
2.15 RNA sequencing (RNA-seq)

RNA was extracted from E200L cells 96 hrs after treatment with 2 µg/ml doxycycline, or control solvent (DMSO), using an RNAeasy kit (Qiagen), then DNase treated, and quality confirmed using an Agilent ScreenTape RNA assay. Two biological replicates were used for RNA-seq (i.e. four samples total). Sequencing libraries were prepared from total RNA (500 ng) using the TruSeq Stranded mRNA Library Preparation kit (Illumina, Inc.) and uniquely barcoded adapters (RNA LT adapters, Illumina, Inc). Libraries were pooled equimolarly for sequencing, which was carried out on the NextSeq500 instrument (Illumina, Inc.) using the NextSeq High Output v2 150-cycle kit (Illumina, Inc.). Approximately 300 million paired reads (passing filter, PF) were obtained, divided between the four experimental samples. NextSeq Control Software Version 2.0.0 and RTA v2.4.6 were used for instrument control and primary analysis, respectively. Reads from the four samples were mapped to the human genome (hg19) using the new Tuxedo Suite of programs (HISAT2, StringTie, Ballgown; https://www.ncbi.nlm.nih.gov/pubmed/?term=27560171). To identify RNA splicing alterations, the four BAM files generated by HISAT2 were used as input for rMATS ([26] http://rnaseq-mats.sourceforge.net/user_guide.htm). Bam files were viewed in the Integrative Genomics Viewer (http://software.broadinstitute.org/software/igv/) to produce Sashimi plots of alternative splicing. RNA-seq data are accessible through GEO Series accession number GSE154496: https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE154496.

2.16 Statistical analysis

Comparisons of two datasets were performed using Students’ t-test or a Mann Whitney U-test, depending on whether the data met the normal distribution. A comparison of three or more groups was performed using one-way analysis of variance (ANOVA) with Dunnett’s post-test, or using Tukey’s pairwise test. The Chipmonk software used for MCIP analysis, and the rMATS software used for RNA-seq analysis, use Benjamini and Hochberg FDR correction for multiple testing. For smaller numbers of samples, Bonferroni correction was used for multiple testing. Numbers of samples quoted in figure legends (n), refer to biological replicates. p<0.05 was considered to indicate a statistically significant difference.
3 RESULTS

3.1 Genome-wide DNA methylation analysis

We used MCIP to identify 225 genes that were hypermethylated in two WT cell lines compared to fetal kidney (figure 1A and supplementary table S2). Gene ontology analysis showed that these genes were particularly involved in chromatin organisation, developmental processes, and transcriptional regulation (figure 1B and supplementary table S4). To distinguish genes that were methylated specifically in WT, two filters were applied; 1) Genes were removed that are polycomb repressive complex marked in embryonic stem cells, since such genes are predisposed to DNA methylation in a wide range of human cancers [27-29] and therefore might not be WT-specific; 2) Positive selection was applied for genes that are upregulated in early nephrogenesis, since their inactivation could induce the MET block that is critical for WT development [2]. Using these criteria, four candidate genes were pinpointed: CHST2, KIT, PTTG1IP and ESRP2 (also known as RBM35B) (figure 1A and supplementary table S2), of which ESRP2 was the most consistently methylated in WT (figure 1C).

ESRP2 was particularly attractive for further study, because of its known involvement in epithelial to mesenchymal transitions in cancer [30]. Support for a role in WT came from examination of the ESRP2 target ENAH. ESRP2 induces inclusion of the epithelial-specific exon 11a in ENAH RNA transcripts [24]. Using RT-PCR, less exon 11A was found expressed in WTs compared to normal kidney (NK) and fetal kidney (FK), consistent with down-regulation of ESRP2 in WT (figure 1D). We therefore went on to examine DNA methylation and expression of ESRP2 in two large cohorts of WTs using pyrosequencing (supplementary figures S3 and S4).
3.2 DNA methylation of ESRP2 in Wilms tumour

The first cohort of WTs from Bristol Children’s Hospital (BCH), consisted of tumour samples of all stages, obtained at surgical resection, pre-chemotherapy. 72% of these WTs were hypermethylated at the ESRP2 (DNA methylation >25%) compared to normal tissue (NT) (figure 2A and supplementary figure S4A). The second cohort from the Royal Marsden Hospital (RMH) were from stages 1 to 3, taken at surgical resection, post-chemotherapy. In this different cohort, 78% of WTs were hypermethylated (figure 2B and supplementary figure S4C). ESRP1 DNA methylation was also tested in the RMH cohort and found to be very low (<2%) in NT and WT, and not significantly different (figure 2B). Additional independent DNA methylation data was extracted for the ESRP1 and ESRP2 promoters from the dataset GSE59157, which showed hypermethylation of ESRP2 in WTs, with much lower methylation of ESRP1, that was only marginally different between NT and WT (figure 2C). Thus, ESRP2 DNA was hypermethylated in three independent cohorts of WTs, but the ESRP2 paralog ESRP1 was not hypermethylated.

There was no significant association between tumour stage and ESRP2 DNA methylation (supplementary figures S5A, B), nor between ESRP2 methylation and survival (supplementary figure S6), nor between tumour histology and ESRP2 methylation (supplementary figure S7A, C).

ESRP2 is located on chromosome 16q22, a chromosomal region showing frequent loss of heterozygosity (LOH) in WT [31]. No difference was observed in the ESRP2 methylation in WTs with or without 16q LOH (supplementary figure S5C).

Most WTs are thought to develop via premalignant lesions (NRs) [3]. To characterise the phase of WT development at which ESRP2 DNA methylation occurs, it was assayed in two sets of matched NK, NR, and WT. ESRP2 was found to be at a similar level of hypermethylation in NRs and matched WTs compared to NKs (figure 2D). In contrast, RASSF1A, a tumour suppressor gene frequently hypermethylated in WT [18], was not hypermethylated in NRs (figure 2D), as previously reported [16]. Methylation values were also extracted for NRs from dataset GSE59157, and similarly, ESRP2 was significantly more methylated in both NR and WT compared to NK (figure 2E), but RASSF1A was only hypermethylated in WTs and not NRs compared to NK (figure 2E).

To investigate whether epigenetic changes, including ESRP2 hypermethylation, are associated with other clinical and molecular features, the BCH cohort of WTs were grouped by hierarchical clustering of DNA methylation values at four loci: ESRP2, the WT1 antisense regulatory region [15], H19 [14] and RASSF1A [18] (supplementary figure S8 and supplementary table S5).
Interestingly, of the 22 WTs studied for WT1 mutations, all six WT1-mutant WTs were in the same cluster (group 3), whereas ten of the WT1 wild-type WTs were in group 1 or 2 and six in group 3 (p=0.015, Fisher exact test). This difference in epigenetic profiles between WT1-mutant and wild-type WTs is supported by similar findings in a recent comprehensive characterisation of molecular defects in WT [7].

ESRP2 DNA hypermethylation was also observed in 10 of 16 (63%) non-WT childhood renal tumours (supplementary figure S9A), especially in clear cell sarcomas of the kidney and in rhabdoid tumours. In datasets GSE73187 and GSE4487, ESRP2 was also found to be hypermethylated in clear cell sarcomas (supplementary figures S9B, C) and rhabdoid tumours (supplementary figure S9C). Interestingly, examination of TCGA data showed DNA methylation changes in ESRP2 in several adult cancers, including hypermethylation in two adult kidney cancers (renal clear cell carcinoma and renal papillary cell carcinoma, supplementary figure S9D). This suggests that epigenetic inactivation of ESRP2 may be involved in the pathogenesis of several types of renal tumours in adults and children, not just in WT.

### 3.3 Expression of ESRP2 in Wilms tumour

In the BCH cohort, expression of ESRP2 in WT was very low compared to NT (figure 3A and supplementary figure S4B) and hypermethylation was associated with reduced expression of ESRP2 (figure 3B). In the RMH cohort, expression of ESRP2 was also reduced in WT compared to NT (figure 3C and supplementary figure S4D), but ESRP1 expression was not significantly different (figure 3C). In dataset GSE2712, ESRP2 expression was lower in WT compared to NT, but ESRP1 expression did not differ significantly (figure 3D). Like methylation results, there was no relationship between ESRP2 expression and tumour histology (supplementary figure S7B, D, E). These results showed that ESRP2 but not ESRP1 expression was reduced in WTs compared to NT and that reduced expression of ESRP2 was associated with hypermethylation. When the two WT cell lines were treated with the DNA methylation inhibitor 5-aza-2'-deoxycytidine (Aza), there was a 5 to 10-fold increase in ESRP2 RNA expression (figure 3E), suggesting a mechanistic link between ESRP2 methylation and gene expression.

### 3.4 Biological function of ESRP2 in vitro

Molecular Oncology (2020) © 2020 The Authors. Published by FEBS Press and John Wiley & Sons Ltd.
The results described above suggested that ESRP2 may have an important functional role in the development of WT. To carry out functional analyses, we initially used transient transfection to constitutively overexpress ESRP genes in WT cell lines 17.94 and Wit49. Overexpression of ESRP2, but not of ESRP1, produced strong growth inhibition in both cell lines (supplementary figure S10). Due to the strong growth inhibition by ESRP2, we were unable to establish stable cell lines using these constitutively active expression vectors. We therefore transfected the WT cell lines with an inducible ESRP2 expression vector (supplementary figure S2). Unfortunately, we were unable to establish a stable cell line from 17.94, but the WT cell line Wit49 was successfully transfected, producing the E200L cell line (V200 was the control cell line transfected with empty vector). E200L showed strong doxycycline-induced expression of ESRP2 RNA (figure 4A) and protein (figure 4B), with the expected nuclear localisation of ESRP2 protein (figure 4D). Induction of ESRP2 drove the splicing of the known target gene ENAH [24] towards its epithelial splice form (+exon 11a; figure 4C), demonstrating that the construct produced biologically active ESRP2 in a WT cell line. There was slight leakiness from the expression vector, with more ESRP2 RNA detected in uninduced E200L cells compared to V200 cells (figure 4A), which probably explains the increased level of ENAH exon 11a in uninduced E200L cells compared to V200 cells (figure 4C).

Over-expression of ESRP2 was associated with an apparent redistribution of actin filaments towards the cell periphery (figure 4D), compared to a more cytoplasmic distribution of actin stress fibres in uninduced cells (figure 4D), as reported in other systems [32, 33].

ESRP2 overexpression caused decreased colony-forming efficiency (figure 4E), as well as reduced growth rate in mass cultures (supplementary figure S11). Real-time analysis of cell density showed a slower cell proliferation rate in the doxycycline induced E200L cells (figure 4F), associated with a small but significant decrease in the rate of cell division (figure 4G, H). Cell invasion (supplementary figure S12A) and cell motility (supplementary figure S12B) showed no changes upon induction of ESRP2 expression.

3.5 Xenograft assays of ESRP2 function in vivo

We used orthotopic xenografts of the Wit49-derived cell lines, under the kidney capsule of nude mice [34] (figure 5), to examine the effect of ESRP2 expression in vivo. After treatment with doxycycline, tumours produced by V200 cells continued to proliferate, whilst tumours produced by E200L cells stopped growing, or regressed (figure 5A and supplementary figure S13A, B). V200
cells produced large tumours in four of five mice, but only one mouse out of five injected with E200L cells (1E-L) produced a large tumour (figure 5B and supplementary figure S13C). Western blotting of excised tumours demonstrated that doxycycline treatment had induced high-level ESRP2 expression in all E200L tumours, with the notable exception of 1E-L (where the tumour grew larger) and V200-induced tumours (figure 5C). This therefore demonstrated a strong correlation between ESRP2 expression and suppression of tumour growth.
3.6 RNA-seq analysis of alternative splicing in Wilms tumour cell lines

In biological duplicates, we carried out RNA-seq on E200L cells that were doxycycline-induced (ESRP2-expressing) or uninduced (non-expressing), obtaining between 70 and 80 million paired-end reads per sample. These reads were mapped onto the human genome, examined for differential gene expression, and used in rMATS software [26] to identify alternative splicing events.

Very few transcripts, apart from ESRP2, showed significant changes in RNA expression (p<0.05, fold change >2) when ESRP2 expression was induced (figure 6A, B). Interestingly, one induced gene was GRHL1, and grainyhead-like transcription factors are important in both kidney development and MET [35], making them good candidates for an involvement in WT. However, we found no difference in expression of GRHL1 between NT and WT (supplementary figure S14), which does not support a role for altered GRHL1 expression in WT pathogenesis.

In contrast to the lack of altered gene transcription, ESRP2 induction was associated with over 900 splicing events involving over 700 genes, with significant changes (False Discovery Rate, FDR<0.05) in skipped exons, mutually exclusive exons and retained introns (figure 6C, supplementary tables S6, S7, S8). The genes involved were particularly enriched for biological processes concerned with vesicular and intracellular transport (supplementary table S9). Although we found many ESRP target genes in common with other reports [36, 37], we also identified over 600 novel target genes (figure 6D). Comparison with a recent study of MET-associated alternative splicing changes during kidney development [38] also revealed overlap with some of our target genes (figure 6E). Interestingly, the two lists of genes identified as overlapping our ESRP2 targets, included five genes (33-36%) in common (CTNND1, CTTN, FLNB, MAP3K7, MPRIP; shown in bold in figures 6D, E), emphasising the importance of ESRP-regulated alternative splicing in kidney development.

We validated a selection of putative targets by specific RT-PCR assays, to examine exon inclusion upon ESRP2 induction. We successfully validated several previously identified targets; CD44, ENAH, FGFR2, SCRIB and SLK (supplementary figure S15), as well as the novel targets LEF1, NPHP1 and RAC1 (figure 6F, G, H). However, some putative target genes showed no altered splicing after ESRP2 induction (supplementary figure S16 and supplementary table S10).

To investigate the possible role of ESRP2 target genes in WT pathogenesis, we examined alternative splicing of 12 genes (seven novel and five previously described) in FK, NK, and WT (figure 7 and supplementary figure S17). Five genes (42%) showed significant changes in the
degree of alternative splicing between normal tissues and WT (figure 7), and seven (58%) did not (supplementary figure S17, supplementary table S10).

4 DISCUSSION

This is the first demonstration of ESRP2 repression caused by DNA hypermethylation in WT, which implicates RNA splicing alterations as an important pathogenic factor in WT development. Investigation of matched sets of NK, NR and WT (figures 2D, E) suggested that inactivation of ESRP2 by DNA methylation occurs at an early stage in kidney development, prior to NR formation. We propose that ESRP2 is essential for the differentiation of the metanephric blastema into nephrons (figure 8B) and that loss of ESRP2 expression causes a differentiation block, initiating NRs, that can undergo further genetic and epigenetic defects to produce WT (figure 8C). Support for this model comes from studies showing that the Esrp paralogs are expressed in the developing kidney [39], with increased expression of Esrp 1 and 2 when renal precursors undergo epithelial differentiation [38], and that knockout of Esrp genes in mice decreases kidney volume, due to a lack of nephrons [40].

Inactivation of ESRP2 as an early premalignant event in WT development, probably explains why we found no association with clinical features (supplementary figures S5, S6). It also explains why we found no association between ESRP2 methylation and LOH at 16q (supplementary figure S5C), where the ESRP2 gene is located, because we have previously demonstrated that 16q LOH occurs after NR formation [14] i.e., after ESPR2 hypermethylation.

We have shown that ESRP1, though an ESRP2 paralogue, is not repressed by hypermethylation in WTs (figure 2B, C, and 3C, D). This implies that ESRP1 and ESRP2 may have different biological functions and are regulated differently in some instances, as recently reported in prostate cancer, where ESRP2 but not ESRP1 is regulated by androgens [41].

Splicing alterations are frequent in human cancers [42], including ESRP-induced changes in breast cancer [43, 33], prostate cancer [44, 41], renal cell carcinoma [45] and colorectal cancer [46]. Most studies have reported expression changes without finding underlying genetic or epigenetic defects in the ESRP genes themselves [46, 43, 45, 41, 33]. However, there are reports of genetic defects in ESRP genes in human cancers, specifically, microsatellite indels [47].
or duplications [44] of ESRP1. In addition, there are reports of DNA methylation changes of ESRP1 in prostate cancer [48] and of ESRP2 in breast cancer [49], and our examination of TCGA data (supplementary figure S9D) demonstrated ESRP2 methylation changes in several other adult cancer types. Thus, our results add to a growing body of evidence that ESRP genes can be either genetically or epigenetically deregulated in a wide range of human cancers.

Our functional studies suggested that the main biological effect of ESRP2 is to regulate cell proliferation by slowing cell division (figure 4E to H and supplementary figure S11). Whilst we observed some actin cytoskeleton rearrangement (figure 4 D), we did not observe significant expression changes in classical epithelial marker genes (figure 6A, B), nor any changes in cell motility or invasion (supplementary figure S12), unlike what occurs when ESRP expression is modulated in adult human cancer cell lines [32, 33, 30]. Coupled with our xenograft experiments that identify ESRP2 as a bona fide tumour suppressor gene (figure 5), these results suggest that the tumour suppressor activity of ESRP2 in WT cell lines occurs mainly by altering cell growth properties, rather than by affecting cellular differentiation.

Mechanistically, our RNA-seq results demonstrated that ESRP2 modulated the splicing of a diverse range of genes, including both well-established and novel targets (figure 6 and supplementary tables S6 to S8). A subset of these genes showed reduced expression of their epithelial splice forms in WT (figure 7), consistent with DNA-hypermethylation induced down-regulation of ESRP2 in WT (figures 2 and 3). Interestingly, of the 728 genes that we identified as having their splicing modulated by ESRP2 (figure 6), only 62 (9%) are WT1 DNA-binding targets [50], whereas 244 (34%) are WT1 RNA-binding targets [51] (figure 8A). The WT1 RNA-binding targets include all five of the ESRP2-regulated genes that we found in common between our results and two other RNA-seq studies (figure 6D, E). This suggests that WT1 and ESRP2 are involved in the post-transcriptional regulation of a similar set of genes during renal development. Since ESRP2 hypermethylation is an early event, like WT1 mutation [52, 53], this suggests that ESRP2 hypermethylation may be another important early event in WT development, which contributes to WT pathogenesis by inhibiting MET (figure 8C). These results, together with genetic evidence showing defects in miRNA-processing genes in WT [8-12], reinforce the critical role that post-transcriptional gene regulation plays in WT pathogenesis.

5 CONCLUSIONS
Our genome-wide DNA methylation analysis of WT has identified ESRP2 as a novel differentially methylated gene. ESRP2 was frequently silenced by DNA hypermethylation in WT, and this occurred early in WT development (in nephrogenic rests). ESRP2 inhibited cellular proliferation in vitro, and in vivo it suppressed tumour growth of orthotopic xenografts in nude mice, demonstrating that ESRP2 acts as a tumour suppressor gene in WT. Using RNA-seq of the ESRP2-expressing WT cell lines, we have identified several novel splicing targets, some of which affect pathways known to be important in kidney development. We propose that epigenetic inactivation of ESRP2 disrupts the regulation of alternative splicing during the mesenchymal to epithelial transition in early kidney development, to generate WT.
AUTHOR CONTRIBUTIONS

D Legge carried out the RNA-seq, target validation and other experimental work, LL performed the animal experiments, WM carried out pyrosequencing, QPCR and derived the inducible cell line, D Lee performed the bioinformatic analysis of the RNA-seq data, MS performed the MCIP DNA methylation analysis, AZ, LP and WYC performed DNA methylation and expression analyses on cell lines and tumours, YA and JB validated putative ESRP2 targets, RW and KPJ provided tumour samples and clinical data, KTAM help devise the methylation analysis strategy, SO planned experiments, especially the animal work and KWB wrote the paper, planned work and carried out some experimental work. All authors viewed the manuscript and were given the opportunity to comment on it.

ACKNOWLEDGMENTS

The authors thank: Professor Herman Yeger (University of Toronto) for the gift of the Wit49 cell line; Prof Russ Carstens (University of Pennsylvania) for the Esrp1/2 plasmids; Dr Madhu Kollareddy for the STR profile of Wit49; the Bristol Genetics Laboratory, Southmead Hospital, for help with pyrosequencing; Dr Paul Bishop for advice about immunofluorescence; Dr. Andrew Herman and Lorena Sueiro Ballesteros for the flow cytometry; and the University of Bristol Genomics Facility for the RNA sequencing work.

DATA ACCESSIBILITY

Supporting data are available in the supplementary material of this article [supplementary figures S1 to S17, and supplementary tables S1 to S10]. The genome-wide DNA methylation (MCIP) data that support the findings of this study are openly available in NCBI's Gene Expression Omnibus and are accessible through https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE153047, GEO Series accession number GSE153047. The RNA-seq data that support the findings of this study are openly available in NCBI's Gene Expression Omnibus and are accessible through https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE154496, GEO Series accession number GSE154496.

FIGURE LEGENDS

Figure 1: Identification of ESRP2 as a candidate hypermethylated gene

A: Venn diagram showing filtering of the 225 methylated genes that were identified by methyl CpG immunoprecipitation (MCIP), firstly by negative selection for genes that are polycomb repressive complex (PRC) marked in embryonic stem cells and secondly by positive selection for genes that are upregulated in the renal vesicle during kidney development. The full list of methylated genes and filtered lists are shown in supplementary table S2. dev., development. B: Gene ontology analysis of the 225 methylated genes. Only categories with a fold enrichment >3 are shown; see supplementary table S4 for full results. C: Bar chart of CHST2, KIT, PTTG1IP and ESRP2 DNA methylation. Controls (Blank, Me 0% (unmethylated DNA control), Me 100% (fully methylated DNA control)), Cell lines (Wilms tumour cell lines, n=2), FK (fetal kidney, n=4), NK (normal kidney, n=2) and Wilms tumours (n=15). DNA methylation was assayed by pyrosequencing; see supplementary table S3 for pyrosequencing primers. D: Alternative splicing of ENAH exon 11A was analysed by RT-PCR followed by agarose gel electrophoresis in 2 WT cell lines (Wit49 and 17.94), FK, NK and 4 WTs. Representative of n=3.

Figure 2: ESRP2 is hypermethylated in Wilms tumours and nephrogenic rests

A: Dot-boxplot of ESRP2 DNA methylation in the BCH cohort. NT (normal tissue) n=8 (4 NK (normal kidney) and 4 FK (fetal kidney), WT (Wilms tumour) n=65, p value from t-test. B: Dot-boxplot of ESRP2 and ESRP1 DNA methylation in the RMH cohort. ESRP2: NT n=18 (all NK), WT n=73; ESRP1: NT n=15 (all NK), WT n=69, p values from t-test. C: Dot-boxplot of ESRP2 and ESRP1 DNA methylation in dataset GSE59157. NT n=36 (all NK), WT n=37, p values from t-test. D: RASSF1A and ESRP2 methylation in nephrogenic rests in the BCH cohort. Two sets of matched NK, NR (nephrogenic rest) and WT are shown. E: Dot-boxplot of RASSF1A and ESRP2 methylation in nephrogenic rests in the GSE59157 dataset. 17 sets of matched NK, NR and WT are shown for RASSF1A methylation and 13 sets for ESRP2 methylation, from individuals where the WT was hypermethylated compared to the matched NK. p values from Tukey’s pairwise test. DNA methylation was assayed by pyrosequencing in A to D and by Illumina Human Methylation 450 bead arrays in E.
Figure 3: ESRP2 expression is repressed in Wilms tumour and regulated by DNA methylation

A: Dot-boxplot of ESRP2 RNA expression relative to FK (fetal kidney) in the BCH cohort. NT (normal tissue) n=6 (3 NK (normal kidney) and 3 FK), WT (Wilms tumour) n=32, p value from t-test. B: Dot-boxplot of ESRP2 expression in hypomethylated versus hypermethylated samples in the BCH. Hypomethylated n=14 (ESRP2 methylation<25%, Hypo), Hypermethylated n=24 (ESRP2 methylation>25%, Hyper), p value from t-test. C: Dot-boxplot of ESRP2 and ESRP1 RNA expression relative to NT in the RMH cohort. ESRP2: NT n=12 (all NK), WT n=51; ESRP1: NT n=9 (all NK), WT n=33, p values from t-tests. D: Dot-boxplot of ESRP2 and ESRP1 RNA expression in the GSE2712 dataset. NT n=3 (all FK), WT n=18, p values from t-tests. E: 17.94 and Wit49 WT cell lines were treated with 2µM Aza (5-aza-2'-deoxycytidine) for six days. ESRP2 RNA levels expressed relative to untreated cells. Results are mean ±SD of n=3, p values from paired t-tests. RNA expression was measured by real-time QPCR, normalized to endogenous levels of TBP in A, B, C and E, and by Affymetrix Human Genome U133A arrays in D.

Figure 4: Inducible expression of ESRP2 in a Wilms tumour cell line

V200 is a control WT cell line (transfected with empty vector) and E200L is a WT cell line expressing doxycycline-inducible ESRP2 (see Materials and Methods). A: ESRP2 RNA expression assayed by QPCR, normalized to endogenous levels of TBP, in V200 and E200L cells after 72 hr doxycycline (Dox) induction, shown as fold induction relative to uninduced V200 cells. Results are mean ±SD of n=3, p value from paired t test. B: ESRP2 protein assayed by Western blotting in V200 and E200L cells after 72 hr doxycycline induction. Anti-ESRP2 detected total ESRP2 protein, anti-FLAG detected vector-derived ESRP2 and anti-ACTIN was used as a loading control. Representative of n=3. C: Alternative splicing of ENAH exon 11A was analysed by RT-PCR followed by agarose gel electrophoresis to detect different sized amplicons, in V200 and E200L cells after 72 hr doxycycline induction. Representative of n=3. D: Immunofluorescence of E200L cells, stained for FLAG-tagged ESRP2 (green) and ACTIN (red) in the left-hand panels, and for nuclear DNA with DAPI (blue) in the right-hand panels, after 72 hr doxycycline induction (+Dox), or uninduced (-Dox). Scale bars = 50 µm. E: Colony-forming assay of induced (doxycycline-treated) and uninduced V200 and E200L cells, shown as fold colony numbers compared to uninduced controls after 14 days. Results are mean ± SD of n=3, p
values from paired t test. F: Cell confluence assay (by IncuCyte), showing growth of induced (doxycycline-treated) and uninduced V200 and E200L cells. Results are mean ± SD of n=6, p value at 162 hrs from paired t test. Representative of n=3. G, H: Cell Trace Violet (CTV) proliferation assay of induced (doxycycline-treated) and uninduced V200 and E200L cells. G: CTV staining of triplicates of induced and uninduced cells showing median fluorescence intensity histograms at 6 days of treatment. Red peaks are controls representing staining of cells at day zero. H: Dot-boxplot of quantitation of staining at 6 days (n=3). p values from paired t tests of log-transformed values.

Figure 5: Tumorigenicity of ESRP2-expressing WT cells

Orthotopic xenografts of V200 and E200L cells were produced by injecting cells under the kidney capsule of nude mice (n=5 for each cell line). When a bioluminescent signal was detected above background (incipient growth of tumours), mice were injected intraperitoneally with doxycycline (Dox) three times per week, as described in Materials and Methods. A: Time course of tumour growth as assayed by in vivo bioluminescence in V200 (left) and E200L (right) xenografts. Plots show tumour signals days after doxycycline induction (i.e., first doxycycline injection = day zero) for each individual mouse. Plot of the average of the bioluminescence traces is shown in supplementary figure S13A. B: Tumours excised from mice (no tumour was excisable in mouse 1B-0 at day 63, therefore only four E200L tumours are shown). Full details of tumour size and weight are shown in supplementary figure S13C. C: Western blot of ESRP2 protein expression in excised tumours.

Figure 6: RNA-seq analysis identifies ESRP2 targets in a WT cell line

RNA-seq was performed on E200L cells with or without 96 hrs of doxycycline induction (to induce high-level ESRP2 expression). A: Volcano plot of p value versus fold induction of transcripts in ESRP2-expressing E200L cells compared to non-expressing cells. Genes induced >2 fold with p<0.05 are indicated in red, and ESRP2 is labelled. B: List of genes in A that were induced >2 fold with p<0.05. C: Number of altered splicing events and affected genes induced by ESRP2 expression. SE; skipped exons, MXE; mutually exclusive exons; RI, retained introns. See supplementary tables S6 to S8 for full details. D: Venn diagram comparing genes identified in this study (SE+MXE+RI) with two other RNA-seq analyses of ESRP-induced splicing changes.
E: Venn diagram comparing genes identified in this study (SE+MXE+RI) with an RNA-seq analysis of MET-associated splicing changes in the developing kidney [38]. F, G and H: Alternative splicing of novel targets *LEF1* (F), *NPHP1* (G) and *RAC1* (H). Left-hand panels: Sashimi plots of RNA-seq data from E500L cells uninduced (-Dox) or induced to express ESRP2 (+Dox). Right-hand panels: Agarose gels of RT-PCRs of amplicons spanning alternatively spliced exons (see supplementary table S1 for primers), in V200 and E200L cells, either uninduced, or doxycycline-induced to produce high-level ESRP2 expression in E200L cells.
Figure 7: Alternative splicing of ESRP2 target genes in Wilms tumour

A to E: Left-hand panels: Representative agarose gels of RT-PCRs of amplicons spanning the alternatively spliced exons (see supplementary table S1 for primers), from FK (fetal kidney), NK (normal kidney), and WT (Wilms tumour). FGFR2 exon IIIb was detected by restriction digest with Aval [24]. Right-hand panels: Dot-boxplots showing percent splice inclusion (PSI) in NT (normal tissue) and WT. p values from t test. ENAH (A), NT n=11 (4 FK and 7 NK), WT n=17; FGFR2 (B), NT n=5 (3 FK and 2 NK), WT n=12; LEF1 (C), NT n=8 (5 FK and 3 NK), WT n=17; SCRIB (D), NT n=5 (2 FK and 3 NK), WT n=9; SLK (E), NT n=5 (2 FK and 3 NK), WT n=8.

Figure 8: ESRP2 action in Wilms tumour

A: Venn diagram comparing the 728 unique genes identified in this study (SE+MXE+RI, skipped exons; mutually exclusive exons and retained introns; figure 6) with 1663 WT1 DNA-binding targets identified by chromatin immunoprecipitation in developing kidney [50] and 4503 WT1 RNA-binding targets (protein-coding genes) identified by RNA immunoprecipitation in M15 mesonephric cells [51]. B: ESRP2 may be required for epithelial differentiation, to form nephrons during kidney development. C: Loss of ESRP2 function by hypermethylation may inhibit normal differentiation and therefore promote persistence of undifferentiated blastema, leading to nephrogenic rest formation and eventual progression to Wilms tumour. B and C adapted from figure 2 in reference [1].
