Global Biogeochemical Cycles®

RESEARCH ARTICLE

10.1029/2024GB008127

Key Points:

- Surface ocean concentration and seaair fluxes of carbon dioxide are estimated at 8‐day, quarter degree resolution with a neural network
- Variability at subseasonal timescales contributes substantially to the total variability of the ocean carbon sink
- The high-resolution data provide novel observational insights into regional and ephemeral processes, such as upwelling and hurricanes

Abstract Measurements of the surface ocean fugacity of carbon dioxide ($fCO₂$) provide an important constraint on the global ocean carbon sink, yet the gap‐filling products developed so far to cope with the sparse observations are relatively coarse $(1^{\circ} \times 1^{\circ}$ by 1 month). Here, we overcome this limitation by using a novel combination of machine learning-based methods and target transformations to estimate surface ocean *f*CO₂ and the associated sea-air CO₂ fluxes (*FCO*₂) globally at a resolution of 8-day by $0.25^\circ \times 0.25^\circ$ (8D) over the period 1982 through 2022. Globally, the method reconstructs *f*CO₂ with accuracy similar to that of low-resolution methods (∼19 μatm), but improves it in the coastal ocean. Although global ocean CO₂ uptake differs little, the 8D product captures 15% more variance in *FCO*₂. Most of this increase comes from the better-represented subseasonal scale variability, which is largely driven by the better-resolved variability of the winds, but also contributed to by the better-resolved $fCO₂$. The high-resolution $fCO₂$ is also capable of capturing the signal of short-lived regional events such as hurricanes. For example, the 8D product reveals that *f*CO₂ was at least 25 μatm lower in the wake of Hurricane Maria (2017), the result of a complex interplay between the decrease in temperature, the entrainment of carbon-rich waters, and an increase in primary production. By providing new insights into the role of higher frequency variations of the ocean carbon sink and the underlying processes, the 8D product fills an important gap.

Plain Language Summary The ocean is important for the climate, as it takes up about a quarter of the carbon dioxide $(CO₂)$ we release into the atmosphere every year. To determine this carbon sink, we measure the levels of carbon dioxide at the surface of the ocean. However, these measurements are limited to the locations where ships and other platforms measure CO₂, leaving gaps in our understanding. To fill in these gaps, statistical methods are used, but previous approaches lack fine‐scale detail. We overcome this limitation with a neural network approach that estimates $CO₂$ in more detail, with estimates every 8 days, at 25 km, compared to the previous 100 km monthly estimates. Globally, our method is as accurate as the previous methods, being slightly more accurate in coastal areas. Although the total amount of carbon the ocean absorbs globally remains consistent, our results show more variability. Our method also detects short-lived local events, such as hurricanes. For example, after Hurricane Maria in 2017, carbon dioxide concentrations at the ocean surface were substantially lower. Overall, our detailed results give us new information on the small-scale changes in the ocean carbon sink and help us fill a gap in our understanding of surface ocean $CO₂$.

1. Introduction

The global ocean plays a pivotal role in limiting global warming by having absorbed approximately 25% of the anthropogenic carbon dioxide (CO_2) emissions over the past two centuries (Gruber, Clement, et al., [2019](#page-23-0); Khatiwala et al., [2013](#page-24-0); Müller et al., [2023](#page-24-0); Sabine et al., [2004\)](#page-25-0). Although this uptake fraction has remained remarkably stable over time (Friedlingstein et al., [2022\)](#page-23-0), the magnitude of the ocean carbon sink has varied substantially around this trend (Bennington et al., [2022;](#page-22-0) DeVries et al., [2023;](#page-23-0) Gruber, Landschützer, & Lovenduski, [2019](#page-23-0); Landschützer et al., [2015,](#page-24-0) [2016;](#page-24-0) McKinley et al., [2020;](#page-24-0) Rödenbeck et al., [2022](#page-25-0)). The strongest evidence supporting this variability comes from observations of the surface ocean $CO₂$ concentration (generally expressed in terms of its fugacity, $fCO₂$), from which the sea-air $CO₂$ flux ($FCO₂$) can be inferred (Fay et al., [2021;](#page-23-0) R. H. Wanninkhof, [2014\)](#page-26-0). Since the *f*CO₂ observations are sparse in time and space, gap-filling techniques are required to map them to the time‐and‐space continuous product needed for estimating the strength of the global ocean carbon sink over time (Fay et al., [2021](#page-23-0); Rödenbeck et al., [2015](#page-25-0)). Most often, statistical or machine learning techniques are used to fill this gap (Chau et al., [2022](#page-22-0); Gloege et al., [2022;](#page-23-0) Gregor et al., [2019](#page-23-0); Iida et al., [2021](#page-24-0); Landschützer et al., [2013](#page-24-0); Rödenbeck et al., [2015](#page-25-0); Telszewski et al., [2009](#page-25-0)), although geospatial and data assimilation‐type methods are also used (Bennington et al., [2022;](#page-22-0) Rödenbeck et al., [2022\)](#page-25-0). Owing to their

Writing – review & editing: Luke Gregor, Jamie Shutler, Nicolas Gruber

global nature and good temporal coverage, satellite observations have proven to be key enablers for all gap‐filling methods (Shutler et al., [2020](#page-25-0), [2024](#page-25-0)).

Typically, these fCO_2 gap-filled products are produced at a monthly $1^\circ \times 1^\circ$ resolution (henceforth denoted by 1M). This resolution has proven to be sufficient to constrain the global ocean uptake of $CO₂$ and its trends and variations (DeVries et al., [2023](#page-23-0); Gloege et al., [2021](#page-23-0); Gruber et al., [2023;](#page-23-0) Landschützer et al., [2016](#page-24-0)) as well as the seasonal variations and their changes over time (Landschützer et al., [2018;](#page-24-0) Rodgers et al., [2023\)](#page-25-0). As a result, these products have played an important role in global assessments, especially those of the Global Carbon Budget (GCB) (Friedlingstein et al., [2022](#page-23-0), [2023](#page-23-0); Hauck et al., [2023\)](#page-23-0). But there is a large amount of variability that current *fCO*₂-products cannot capture, especially at the regional and subseasonal scale. Modeling studies and observations at these scales have regularly revealed *fCO*₂ variations that exceed those seen in the 1M products (Arruda et al., [2015;](#page-22-0) Friederich et al., [2008](#page-23-0); Nicholson et al., [2022;](#page-24-0) Resplandy et al., [2024](#page-25-0); Turi et al., [2014](#page-25-0); Yu et al., [2020](#page-26-0)). These variations are driven by finer‐scale temporal features such as storms and upwelling events, but also by finer‐scale spatial features, such as those associated with mesoscale circulation or strong fronts. In addition, high-frequency variations in surface winds contribute to high frequency variations in the sea-air $CO₂$ fluxes as well (Whitt et al., [2019](#page-26-0)).

Our current ability to constrain such high-resolution FCO_2 and fCO_2 variability from observations is very limited. This is, in no small part, a consequence of the segmented way the ocean $CO₂$ system is currently sampled (R. Wanninkhof et al., 2019). On the one hand, we have underway $CO₂$ measurements from ships that give a good perspective of the variability in space along a limited number of survey lines (Jones et al., [2012](#page-24-0)). On the other hand, we have time series observations from a few sites that provide detailed temporal information (Bates et al., [2014](#page-22-0); Ye et al., [2020\)](#page-26-0). But we rarely have observations that cover both time and space in a synoptic manner.

The few observation‐based studies clearly point to the scale of the challenge. Regarding high‐frequency temporal variability, a glider-based study in the Southern Ocean found that mid-latitude cyclones can induce variability up to 20 μatm within a frequency range of 1–10 days (Nicholson et al., [2022\)](#page-24-0). Another glider‐based study suggested that *pCO*₂ measurements need to be taken every 3 days to constrain uncertainty in dynamically variable regions (Monteiro et al., [2015\)](#page-24-0). Beyond the Southern Ocean, intense sporadic events like tropical cyclones and hurricanes can cause *p*CO₂ fluctuations as large as 50 µatm within a two-day window (Bates et al., [1998](#page-22-0); Koch et al., [2009](#page-24-0); Yu et al., [2020\)](#page-26-0). Mooring‐based studiesfrom variouslocations have also revealed variations of more than 50 μatm within days to weeks (Leinweber et al., [2009](#page-24-0); Pardo et al., [2019](#page-25-0); Sutton et al., [2014](#page-25-0), [2017](#page-25-0); Torres et al., [2021\)](#page-25-0).

Regarding high‐resolution spatial variability, gradients exceeding several tens of μatm over tens of kilometers are regularly encountered along ship‐tracks, especially in dynamic regions such as the Southern Ocean and boundary current regions. This leads to short spatial autocorrelation length scales (Jones et al., [2012](#page-24-0)). Although the length scales for *FCO*₂ and *fCO*₂ are typically around 100 km or more in open ocean gyre regions, they decrease to less than 50 km in these dynamic regions (Jones et al., [2012;](#page-24-0) Murphy et al., [2001](#page-24-0)). These findings are corroborated by studies using drifters and uncrewed surface vehicles in the Northeastern Atlantic and the Southern Ocean, which have reported spatial gradients of *p*CO₂ on the order of 10 μatm over 20 km (Boutin et al., [2008;](#page-22-0) Merlivat et al., [2009;](#page-24-0) Sutton et al., [2021](#page-25-0)).

Better resolution of the fine-scale variations of the sea-air $CO₂$ fluxes matters for multiple reasons. First, it allows us to better resolve a number of key processes that govern the ocean uptake of $CO₂$, providing novel insights into how the ocean carbon sink functions. Second, it allows us to assess the role of potential aliasing effects resulting from missing variability, potentially aliasing our estimate of global ocean carbon uptake (Koch et al., [2009\)](#page-24-0). Third, such high-resolution products can also provide critical constraints for assessing the impact of natural or man-made perturbations, such as those associated with marine heatwaves (Mignot et al., [2022](#page-24-0)) or the purposeful release of alkaline substances to enhance the oceanic uptake of atmospheric $CO₂$ (González & Ilyina, [2016](#page-23-0); Lenton et al., [2018\)](#page-24-0).

First attempts to cover global finer-scale variability than 1M in gap-filled *f*CO₂ products were undertaken by Rödenbeck et al. ([2014\)](#page-25-0) for the CarboScope Mixed‐Layer Scheme (CarboScope‐MLS) and by Chau et al. ([2024\)](#page-22-0) for the CMEMS-FFNN product. The CarboScope-MLS, while having higher temporal resolution (daily), suffers from its coarse spatial resolution of $>2^{\circ}$. CMEMS-FFNN offers superior spatial resolution, but resolves $fCO₂$ only at monthly resolution. These limitations are, in part, technological in nature. For example, the commonly used Surface Ocean CO₂ Atlas (SOCAT) provides a monthly $1^{\circ} \times 1^{\circ}$ resolution gridded product alongside the

ungridded cruise tracks (Sabine et al., [2013\)](#page-25-0). Similarly, remote sensing and reanalysis products are often available at monthly resolutions in addition to daily files. However, there are some studies that have estimated highresolution *f*CO2 (∼5 km) at regional scales, for example, the Gulf of Mexico (Chen et al., [2019](#page-22-0)) and the South China Sea (Sharp et al., [2022;](#page-25-0) Song et al., [2023\)](#page-25-0). The regional constraint of these studies allows for simpler machine learning architecture (e.g., no clustering) that is able to predict $fCO₂$ with greater fidelity than global approaches.

In this study, we aim to bridge the "high-resolution gap" in current *f*CO₂ products by generating estimates at an 8– day, $0.25^{\circ} \times 0.25^{\circ}$ (henceforth referred to as 8D) resolution for both *f*CO₂ and *FCO*₂. To achieve this, we introduce a novel combination of machine learning‐based methods and also use a number of target transformations. This allows us to improve the resolution of our previously published OceanSODA‐ETHZ product (Gregor & Gruber, [2021](#page-23-0)), which had a resolution of $1^{\circ} \times 1^{\circ}$ by monthly to the desired 8D resolution. We refer to the 8D product as OceanSODA‐ETHZv2.

The paper is organized as follows: First, we outline the data sets and methodology that underlie our innovative technique. Following this, we rigorously evaluate the model's output. We then explore the implications of highresolution *p*CO₂ data on *FCO*₂ variability across different temporal scales. Finally, we assess the local and global impact of these high-resolution estimates, including a case study focused on the influence of a hurricane.

2. Methods

2.1. The OceanSODA‐ETHZv2 Method

2.1.1. Design Elements

The method used for the OceanSODA‐ETHZv2 product is a classical machine learning‐based regression approach to map the sparsely observed $fCO₂$ data to the global surface ocean. To achieve the mapping at the 8D target resolution, while maintaining robustness and scalability, several design elements are implemented, most of which build on the ideas of other studies.

The first design element concerns the target variable. We first subtract atmospheric $CO₂$ in order to remove most of the trend in the target variable (Ma et al., [2023](#page-24-0)). Thereafter, following Bennington et al. [\(2022](#page-22-0)), we remove the temperature effect from oceanic *f*CO₂ leaving the non-thermal, that is, chemically driven, part of the signal. These two transformations capture the impact of two well-understood and quantifiable drivers, such that the machine learning part is focused on the variability imparted on *f*CO₂ through the other drivers, such as biology and mixing (Sarmiento & Gruber, [2006](#page-25-0)).

The second design element is that we use an 8-day climatology of $ΔfCO₂$ as a predictor. This is inspired by the works of Landschützer et al. ([2015\)](#page-24-0) and Denvil-Sommer et al. [\(2019](#page-23-0)), both of which include information on the *fCO*₂ seasonal cycle, the dominant mode of variability. The first study does this through clustering based on a predefined monthly climatology of *fCO*₂, and the second by removing the monthly climatological signal from *f*CO₂ before training their neural network. We produce this seasonal climatology in a separate initial step.

The third design element is that we combine decision-trees and neural-networks. For the estimation of the climatological seasonal cycle, we use Gradient‐Boosted Decision Trees (GBDT), thus taking advantage of the low bias nature of tree-based approaches. For the estimation of the time-varying *f*CO₂, we use a feed-forward neural network method. Theoretically, the differentiable nature of FFNNs better captures the relationships (i.e., gradients) between the $fCO₂$ and its drivers (Holder & Gnanadesikan, [2021\)](#page-24-0).

The fourth and final design element is that we include the rate of change of the drivers as predictors. More specifically, the difference between the current and the previous time step is used for variables such as temperature and chlorophyll‐a. This gradient adds additional information about the rate of change and further improves the stability of the *f*CO₂ predictions between time steps.

Overall, this set of design choices improves the stability and robustness of our estimates and improves computational efficiency (compared to other methods), which is important given that the amount of data increased by a factor of ∼61 by going from the typical 1M resolution to 8D.

Figure [1](#page-3-0) summarizes the 6 steps involved in the estimation of fCO_2 and FCO_2 : (a) Data preparation and preprocessing, including the detrending of the target variable by subtracting the atmospheric $CO₂$ mixing ratio to

Figure 1. Diagram showing the 6 steps in our approach. (a): Step 1: Data preparation and pre-processing (Figure [2](#page-4-0), Section [2.1.2\)](#page-4-0). Notably, we remove the atmospheric CO_2 trend from SOCAT fCO_2 by removing the mole fraction of CO_2 in the marine boundary layer (xCO_2^{nbl}) . This yields the variable Δ^*CO_2 . (b) Step 2: An 8-day climatology of Δ*CO₂ is estimated and used as a predictor in step 4 (Section [2.1.3](#page-5-0)). To this end, we use Gradient Boosted Decision Trees (GBDT). (c) Step 3: The target variable is transformed by removing the anomalous thermal component, fCO_2^T (after Bennington et al., [2022\)](#page-22-0) (Section [2.1.5\)](#page-5-0). The resulting non-thermal component, $\Delta^*CO_2^{\text{nonT}}$, is used as the target for the next step. (d) Step 4: An ensemble of 35 FFNNs predicts $\Delta^*CO_2^{\text{nonT}}$ at 8D resolution (Section [2.1.5\)](#page-5-0). (e) Step 5: Reverse transformation: The thermal component $(f\text{CO}_2^T)$ and the atmospheric trend $\left(x\text{CO}_2^\text{mbl}\right)$ are added back to arrive at the estimate of $f\text{CO}_2$. (f) Step 6: Calculate the sea-air CO_2 fluxes with the output from the previous step (Section [2.1.7\)](#page-6-0).

form the variable Δ^*CO_2 . (b) Machine learning Part 1: Estimation of the 8-day climatology of Δ^*CO_2 ; (c) Removal of the thermal component from Δ^*CO_2 to form the variable $\Delta^*CO_2^{\text{nonT}}$; (d) Machine learning Part 2: Estimation of the time-variable non-thermal target $\Delta^*CO_2^{\text{nonT}}$; (e) Reverse transformation of $\Delta^*CO_2^{\text{nonT}}$ to obtain the time-variable *f*CO₂ field; (f) Estimation of the sea-air CO₂ fluxes, *FCO*₂. The methods section, in large,

Figure 2. A Gantt chart showing the various data sets used for the OceanSODA-ETHZv2 product. Each variable is represented by a color, with each product having its own horizontal bar and the thinner, lighter shaded bars represent the periods over which the climatology was calculated for that variable. In the case of salinity, where products overlap in time, the high-latitude and coastal gaps of the ESA-CCI product are filled by the CMEMS-Multiobs product, with ESA-CCI always taking priority.

describes these steps in greater detail. Furthermore, we describe the decomposition of the sea-air $CO₂$ fluxes into different temporal modes of variability.

2.1.2. Step 1: Data Preparation and Preprocessing

We obtain *f*CO₂ from the SOCAT v2022 cruise track data set (D. C. Bakker et al., [2016;](#page-22-0) D. C. E. Bakker et al., [2023\)](#page-22-0), retaining data with a quality flag of D or higher. These observations are then binned to a regular grid with a resolution of 8-day by $0.25^{\circ} \times 0.25^{\circ}$. No weighting is applied during the binning, meaning that the data is analogous to the unweighted $fCO₂$ data from the gridded SOCAT product. We then remove the atmospheric $CO₂$ component from the data using the 7-day, latitudinally resolved CO₂ concentration in the marine boundary layer $(xCO₂^{mbl})$ from Lan et al. ([2023\)](#page-24-0):

$$
\Delta^* \text{CO}_2 = f \text{CO}_2^{\text{SOCAT}} - x \text{CO}_2^{\text{mb}!}. \tag{1}
$$

For detrending, we use *x*CO₂ rather than atmospheric *f*CO₂ to avoid any unwanted impact of variations in at-mospheric pressure and vapor pressure (see Equation [4](#page-6-0) for the calculation of atmospheric *fCO*₂).

For the predictors, we use sea surface temperature (SST; Merchant et al., [2019\)](#page-24-0), salinity (Boutin et al., [2018](#page-22-0); Carton et al., [2018;](#page-22-0) Droghei et al., [2016](#page-23-0)), sea surface height (SSH; Taburet et al., [2019](#page-25-0)), chlorophyll‐a (CHL; Sathyendranath et al., [2023\)](#page-25-0), mixed-layer depth (MLD; Carton et al., [2018](#page-22-0)), and the atmospheric CO_2 concentration at Mauna Loa (*x*CO₂^{atm}; Tans & Keeling, [2023](#page-25-0)) (see Figure 2). An important consideration for the selection of the predictor variables and their sources was their availability at 8D resolution or better. This is achieved for all predictors except for MLD and SSS, which are available only at a resolution of 5 days by 0.5°. Our set of pre-dictors is rather similar to that used by most other gap-filling methods (Chau et al., [2024;](#page-22-0) Rödenbeck et al., [2015\)](#page-25-0).

Pre-processing and transformation (Figure [1a\)](#page-3-0) of these predictor variables can be separated into: (a) Regridding the predictor variables to the target 8D resolution. For SST, SSH, and CHL this means downgrading the resolution in time from daily to 8‐day resolution and in space from ∼5 km (SST and CHL). For MLD and SSS, this means downgrading in time (5‐day to 8‐day), but upgrading in space (from 0.5° to 0.25°). (b) variable stacking for salinity, and gap‐filling for CHL, (c) separation of anomalies from climatologies (*clim, anom*), (d) calculating the 19449224, 2024, 8, Downloaded from https://agupubs.onlinetibrary.wiley.com/doi/10.1029/20240B008127 by Test, Wiley Online Library on [23.08/2024], See the Terms

and Cond

conditions) on Wiley Online 1

library for rules

of use; OA

difference between the current and previous time step (*delta*) which is used as a predictor. For the full description of how these data were prepared, see Text S1 in Supporting Information S1.

2.1.3. Step 2: Estimation of an 8‐Day Climatology

We estimate the quarter-degree 8-day climatology of Δ^*CO_2 using Gradient Boosted Decision Trees. We use seasonal climatologies of SST, SSS, CHL, MLD, and SSH as predictors along with transformations of the time and space coordinates (Figure [2\)](#page-4-0) — see SText S1 in Supporting Information S1. The estimated $\Delta^*CO_2^{\text{clim}}$ is smoothed with a rolling mean with a 2-month by 0.75° window (seven 8-day time steps) to avoid overfitting to the subseasonal variability still included in the target. We choose a large temporal window, but narrow spatial window to preserve spatial gradients, particularly in coastal regions.

2.1.4. Step 3: Target Transformation

The target, $\Delta^*CO_2^{nonT}$, is estimated by removing the anomalous thermal component of fCO_2 (Figure [1c](#page-3-0)), after Bennington et al. [\(2022](#page-22-0)):

$$
\Delta^* \text{CO}_2^{\text{nonT}} = \Delta^* \text{CO}_2 - \underbrace{\left(\Delta^* \text{CO}_2^{\text{elim}} + 367 \text{ \mu atm}\right) \cdot 0.0423 \cdot \Delta \text{T}}_{\text{thermal component}},\tag{2}
$$

where, $\Delta^*CO_2^{\text{elim}}$ is the spatially resolved long-term mean of Δ^*CO_2 from (Step 2) including an offset of 367 µatm (an estimate of the mean oceanic $fCO₂$ over the study period), and ΔT is the anomaly of sea surface temperature relative to its 8‐daily climatology (similar to Bennington et al., [2022](#page-22-0)). We do not include the seasonal component of temperature, since seasonal information is already included in $\Delta^*CO_2^{\text{elim}}$.

2.1.5. Step 4: Estimation of $\Delta^* \text{CO}_2^{\text{nonT}}$

We use a Feed-Forward Neural Network to estimate $\Delta^*CO_2^{nonT}$. This choice is based on the work of Courtois et al. [\(2023\)](#page-22-0), who demonstrate that such networks are able to extrapolate beyond training observations. In addition, neural networks were shown to be better able to capture the true relationship between a target variable and its predictors (Holder & Gnanadesikan, [2021\)](#page-24-0).

Predictor variables for this second machine learning step include the climatology of Δ^*CO_2 from step 2, all other predictors (SST, SSS, CHL, MLD, and SSH) as anomalies, together with their 8‐day climatologies, and the differences between the current and previous time step. The atmospheric $CO₂$ trend from Mauna Loa is included as the final predictor.

The 8D binned *f*CO₂ data and the colocated predictors are split into training, testing, and validation subsets. We use the same approach as Bennington et al. [\(2022](#page-22-0)) where every seventh month is considered a test (or validation) month. The validation subset uses the same 7-month split, but with a 3-month offset. The validation split is used to avoid overfitting by the FFNN by stopping training when no improvement is observed. Test data are not used during training of the FFNN and are used to assess performance. Given the structure of our splits, seven train-testvalidation splits can be created by starting on a different month in 1982 (January through July), which means that we can fully reconstruct the SOCAT cruise tracks with only test splits (Figure S1 in Supporting Information S1).

We use an ensemble of FFNNs to predict $Δ*CO₂$, with five FFNNs per train-test-validation split. Together with the 7 splits, this results in a total of 35 ensemble members. We use TensorFlow and Keras to construct our neural network ensemble (Abadi et al., [2015](#page-22-0)). Each ensemble member has two hidden layers with 64 and 32 neurons with ReLu activation (see Text S2 in Supporting Information S1).

2.1.6. Step 5: Retransformation

The output of the FFNNs is first transformed back to Δ^*CO_2 from $\Delta^*CO_2^{\text{nonT}}$ using the thermal component of Equation 2. The Δ^* CO₂ variable is then further transformed back to *f*CO₂ using Equation [1.](#page-4-0) All 35 ensemble members are then averaged for the estimates of *f*CO₂ and the standard deviation of the ensemble is calculated (σ_{ens}) .

2.1.7. Step 6: Calculation of Fluxes

We calculate sea-air CO_2 fluxes (FCO_2) using the bulk formulation:

$$
FCO_2 = K_0 \cdot k_w \cdot (fCO_2 - fCO_2^{\text{atm}}) \cdot (1 - ice),
$$
\n(3)

where K_0 is the solubility of CO_2 in seawater from Weiss [\(1974](#page-26-0)), k_w the gas transfer velocity (R. H. Wannink-hof, [2014](#page-26-0); Sarmiento & Gruber, [2006\)](#page-25-0), *f*CO₂ is the surface ocean CO₂ fugacity predicted by the OceanSODA-ETHZv2 method, fCO_2^{atm} is the atmospheric marine boundary layer CO_2 fugacity, and *ice* is the sea-ice fraction from the temperature product shown in Figure [2.](#page-4-0) The sign convention is that a positive flux in Equation 3 is upward, that is, indicating outgassing of oceanic $CO₂$.

Atmospheric *f*CO₂ is calculated from the dry air mixing ratio of atmospheric CO₂ in the marine boundary layer from NOAA, that is, xCO_2^{mbl} (Lan et al., [2023](#page-24-0)):

$$
f\text{CO}_2^{\text{atm}} = x\text{CO}_2^{\text{mbl}} \times (P_{\text{atm}} - p\text{H}_2\text{O}) \times \text{virial factor},\tag{4}
$$

where P_{atm} is the mean sea-level pressure from ERA5 (Hersbach et al., [2020](#page-23-0)), pH_2O is the partial pressure of water vapor based on Weiss and Price ([1980\)](#page-26-0), and the *virial factor* accounts for the non-ideal behavior of CO₂ (Weiss, [1974](#page-26-0)). For k_w , we use the quadratic formulation of the sea-air CO₂ fluxes from R. H. Wanninkhof ([2014\)](#page-26-0) scaled for ERA5 winds:

$$
k_{w} = 0.274 \cdot U_{10}^{2} \cdot \left(\frac{Sc}{660}\right)^{-1},
$$
\n(5)

where U_{10}^2 is the second moment of the wind speed, and *Sc* is the Schmidt number for CO_2 (Jähne et al., [1987\)](#page-24-0). The second moment of the wind speed is calculated from the hourly ERA5 wind speed, which is not available in the output but can be estimated from the wind vector components *u* and *v* with $u^2 + v^2$. U²₁₀ is then regridded in the time dimension to match the resolution of our output. The coefficient of gas transfer (0.274) was obtained by ensuring that the global mean gas transfer coefficient for the period 1990 and 2019 and for the ice-free ocean matches the constraint of $k_w = 16.5 \pm 3.2$ cm hr⁻¹ (Fay et al., [2021;](#page-23-0) Naegler, [2009;](#page-24-0) Sweeney et al., [2007](#page-25-0)).

2.2. Decomposition of Fluxes

We decompose the temporal variability of the sea-air $CO₂$ fluxes into three modes by integrating the frequencies in the Fourier domain (after Gu et al., [2023](#page-23-0)): subseasonal, <3 months frequencies; seasonal, 3 to ∼15 months frequencies; and interannual, >15 months frequencies. In some cases, we further separate the interannual variability into sub‐decadal (15 months–8 years) and decadal (>8 years) variability. For the Fourier decomposition, we assume that all time steps have the same length, that is, $\frac{365}{46}$ days for the high-resolution 8D product and $\frac{365}{12}$ days for the 1M low‐resolution product.

To identify the drivers of the sea-air CO₂ flux variability, we apply a Reynolds decomposition $(y = \overline{y} + y')$ to Equation 3. We thereby combine k_w and K_0 as the gas transfer coefficient $k_x = K_0 \cdot k_w$, in order to focus on the role of the wind variability (Doney et al., [2009\)](#page-23-0)—the temperature dependencies in k_w and K_0 account for <1% of the variability of k_x (Woolf et al., [2016](#page-26-0)). We also look only at the role of the sea-air difference in fCO_2 , that is, ΔfCO_2 , since the variability of atmospheric fCO_2 is much smaller than that of the oceanic fCO_2 . Furthermore, we neglect the role of sea-ice variations. With these simplifications, we decompose the sea-air CO_2 flux, FCO_2 , as follows:

$$
FCO_2 = \overline{k_x} \cdot \overline{\Delta fCO_2} + k_x' \overline{\Delta fCO_2} + \overline{k_x} \Delta fCO_2' + k_x' \cdot \Delta fCO_2'.
$$

\nmean state
\nwind variability
\n
$$
fCO_2 \text{ variability}
$$
\n
$$
fCO_2 \text{initial}
$$

Since we are interested in the variability of $FCO₂$ we do not have to consider the first term where the long-term averages are taken for both variables. We calculate the variability as representations of the variance (σ^2) . If we represent each of the terms in Equation 6 as *a*, *b*, and *c* respectively, the total variance is given by:

$$
\sigma^{2}(a+b+c) = \sigma^{2}(a) + \sigma^{2}(b) + \sigma^{2}(c)
$$

+2 \cdot cov(a,b) + 2 \cdot cov(a,c) + 2 \cdot cov(b,c).
covariances \approx residual (7)

Given that we calculate the variance from the frequency domain, we calculate the covariance for the different modes of variability as the residual of the total and summed variances. The fraction contribution by each term is computed as:

$$
\frac{\sigma^2(\text{wind})}{\sigma^2(\text{total})}, \frac{\sigma^2(f\text{CO}_2)}{\sigma^2(\text{total})}, \frac{\sigma^2(\text{cross term})}{\sigma^2(\text{total})}, \frac{\text{covariances}}{\sigma^2(\text{total})}.
$$
\n(8)

Note that since the covariances can be negative, the fractional contribution can also be negative.

3. Evaluation and Assessment

We first evaluate the 8D *f*CO₂ product estimated by OceanSODA-ETHZv2 by determining the large-scale offsets against the test and training data, and by comparing these offsets against the ensemble spread that we use as an estimate of the prediction uncertainty. We then investigate in what way the high-resolution product is able to capture finer-scale structures in time and space. To this end, we focus on high-frequency observations from open ocean and coastal mooring stations (Sutton et al., [2019\)](#page-25-0). We also assess how well the high-resolution estimates can track high‐resolution spatial features observed along cruise tracks.

3.1. Uncertainties

To determine the bias and root mean squared differences (RMSD) of the 8D product against the SOCAT data, we rely only on predictions that have not been used to train the subset of ensemble members. Given that we use an ensemble of results where the starting month changes (1–7), we have a complete representation of the SOCAT data set (Figure S1 in Supporting Information S1; Gregor et al., [2019;](#page-23-0) Bennington et al., [2022](#page-22-0)).

The unweighted bias and RMSD for the *f*CO₂ are low at a global scale at −0.06 μatm and 19.2 μatm, respectively (Table S2 in Supporting Information S1), where a negative bias indicates that OceanSODA‐ETHZv2 underestimates *f*CO₂ relative to SOCAT. The open (coastal) ocean has a bias of 0.07 μatm (−0.23 μatm) and an RMSD of 13.0 μatm (25.4 μatm) (Figure [3,](#page-8-0) Table S2 in Supporting Information S1), where the coastal ocean is defined as the ocean region within 300 km from the coast or the 1,000 m isobath (Laruelle et al., [2017](#page-24-0); Resplandy et al., [2024](#page-25-0)). Given the spatial and seasonal inhomogeneity in the SOCAT observations, biases and RMSDs are also assessed over time and space (Figure [1](#page-3-0) with weighted averages). We assess both metrics for three latitude bands: the high northern (blue lines; >35°N) and southern latitudes (yellow lines; >35°S) and the bounded lower latitudes (red).

Biases are larger and more variable before 2000 when the observations are more sparse (Figure [3a](#page-8-0)). The spatial separation also reveals that biases compensate meridionally, resulting in lower global biases due to aggrega-tion. There is no seasonality in the biases in any of the latitude bands. Spatially (Figure [3e\)](#page-8-0), biases are mostly low (|*bias*| < 2.5 μatm), except for the coastal regions and a few open ocean regions, for example, the southern Indian Ocean, where there is a positive bias (red in Figure [3e](#page-8-0)).

In northern high latitudes, RMSD increases slightly over time (∼15 to >20 μatm; blue line in Figure [3c](#page-8-0)). This is likely due to the increase in the variance of the training data over time, particularly in the coastal ocean, where there is typically higher biogeochemical complexity (Figure S2). The RMSD for the tropics and southern regions remains constant (∼15 μatm) throughout the 40‐year period, with no significant slope. On average, RMSDs are larger in the summer months compared to the winter months (∼25 μatm vs. ∼15 μatm) of both the northern and southern high latitudes (blue and yellow lines in Figure $3d$). The seasonality of the RMSD in the low latitudes (red line in Figure [3d](#page-8-0)) is lower by comparison, but has a slight bias to the Northern Hemisphere summer, likely due to sampling bias.

At a global scale, the spatial distribution of the RMSD resembles the ensemble standard deviation (σ_{ens}) with a spatial correlation r^2 of 0.65 for the time averaged maps (Figure [4\)](#page-9-0). This suggests that the ensemble spread is a

Global Biogeochemical Cycles 10.1029/2024GB008127

Figure 3. Metrics using test-data estimates (unseen by the machine learning model). Time series on the left show latitudinally averaged biases (a) and root mean squared difference (RMSD in c) with a 1‐year rolling mean applied. The legend also contains the time‐averaged mean values (in μatm) weighted by number of samples. The smaller time series figures on the right show seasonally averaged biases (b) and RMSD (d). The maps below show test bias (e) and RMSD (f) with the values showing the spatial average of the respective metrics weighted by area.

good indicator of the spatial structure of the quality of the estimated *fCO*₂. This relationship was exploited by Chau et al. ([2024\)](#page-22-0) who scaled *σ*ens to match the RMSD as closely as possible. Here, we follow the same idea to obtain a global map of uncertainty of our 8D product, but we simply multiply *σ*ens with a factor of 5.7 (Figure [4\)](#page-9-0), that is, the global mean ratio of $\frac{RMSD}{\sigma_{ens}} = \frac{11.3}{2.0}$.

3.2. Assessing Spatial and Temporal Scales of Variability

The benefit of estimating high-resolution *fCO*₂ becomes most obvious when comparing the estimated product against the raw observations in SOCAT. The majority of the SOCAT data set consists of ship cruise tracks. In Figure [5,](#page-10-0) we compare three representative cruise tracks in the Atlantic and Pacific with the OceanSODA-ETHZv2 test-subset of *fCO*₂, where the test-subset is a subset of our output that has not been trained with the data it estimates. Along all three tracks, the large-scale variability of the SOCAT *fCO*₂ observations is well represented. In open ocean regions, the RMSD scores are actually substantially lower than the global average. An exception to this occurs in poorly sampled regions, such as the South Atlantic gyre (Figure [5d,](#page-10-0) where the regional biases can be >|5| μatm.

Most important is that our high-resolution product captures a substantial fraction of the fine-scale structures contained within the observed *f*CO₂. For example, the 8D product properly represents the strong outgassing signals associated with the upwelling driven by the gap winds off the coast of Central America (Figure [5a](#page-10-0)). The

Figure 4. (a) The long-term mean of *fCO*₂ for 1982 to 2022 and (b) the scaled standard deviation (5.7 σ) of the 35 ensemble members.

impact of these winds, the Tehuano and Papagayo jets, on the surface ocean $CO₂$ system on ocean biogeochemistry can be clearly seen, extending in the case of the Papagayo jet all the way into the region of the Costa Rica dome (Chapa‐Balcorta et al., [2015](#page-22-0); Fiedler, [2002\)](#page-23-0). These features are generally not well captured by the global 1M products (Figure S4 in Supporting Information S1). Further, the 8D product adequately captures the magnitude of the equatorial upwelling in both the Atlantic and Pacific (Figures [5c](#page-10-0) and [5d\)](#page-10-0), as well as the strong variations off the coast of Europe (Figure [5d\)](#page-10-0).

At the same time, there are clear limits in our 8D product. The specific structure of the upwelling signal associated with the gap winds is missed, as is the exact location of the equatorial upwellings offset. Furthermore, the signals of two tropical instability waves in the equatorial Pacific (Figure $5c$) are completely missed by the 8D product. This is largely a consequence of these features having a propagation speed of around 30 km day⁻¹ (Legeckis, [1977\)](#page-24-0), such that an 8-day resolution ∼25 km product is insufficient to correctly capture their dynamics. Finally, the neural network cannot capture some extremely sharp gradients observed near New Zealand (Figure [5c](#page-10-0)). However, our 8D product captures the observed variations in *fCO*₂ much better than the 1M products (see Figure S4 in Supporting Information S1).

Similar successes and limitations of the 8D product can be identified when comparing it with high‐frequency observations from long‐term moorings. In Figure [6](#page-11-0), we show comparisons of our 8D product with observations from four open‐ocean and one coastal mooring programs in the Pacific and the Pacific sector of the Southern Ocean (Sutton et al., [2019](#page-25-0); D. C. Bakker et al., 2016). The observed $fCO₂$ is well represented by the estimated $fCO₂$ at locations with a large seasonal cycle. The 8D product captures 66% of the variability observed at the coastal California Current Ecosystem 1 (CCE1)

mooring 140 mi (ca. 225 km) off the coast of California (Figure [6a\)](#page-11-0), 82% at the SOFS mooring south of Tasmania (Figure [6e](#page-11-0)) and 72% at the STRATUS mooring site off the coast of South America (Figure [6f](#page-11-0)). Also, shorter‐term variations are generally well captured at these three sites. The performance of the 8D product is somewhat weaker at the other two sites. While the *fCO*₂ estimates at the PAPA mooring location (Figure [6b](#page-11-0)) are able to represent most of the seasonal variability, some extremes are not captured. This leads to only 50% of the observed variability being captured by the 8D product. In the equatorial Pacific (TAO125W in Figure [6d\)](#page-11-0) the 8D product appears to miss a substantial fraction of the high‐frequency variability. Much of this variability is caused by equatorial instability waves. This mismatch is consistent with the mismatches seen in the Equatorial Pacific when analyzing the cruise‐line data (Figure [5c\)](#page-10-0).

Comparisons with a larger set of moorings reveal similar strengths and limits (Table S4). For example, our 8D product reproduces the observed variations at the WHOTS mooring near Hawaii exceptionally well. But it struggles to capture the variations at the very coastal CCE2 mooring off the coast of California. This follows the previously identified pattern, with our 8D product reproducing the observations best in regions where the seasonal cycle dominates, while it performs less successfully in regions where high-frequency variations dominate. This confirms our previous findings that while our product made a substantial step forward in reproducing higher frequency variations, it is still too coarse to capture all of them. This is also in part due to the fact that our method has a propensity to adhere to the seasonal cycle, which is very helpful overall, as this allows us to capture the dominant signal of variability over most of the ocean. Although this increases the robustness of the method, it comes at a cost.

4. Patterns and Variability of *f***CO2**

4.1. Representation of High‐Resolution Features

Recognizing some shortcomings of our high-resolution mapped *f*CO₂ product, it is instructive to visualize its strengths in representing fine-scale features previously not seen in gap filled *fCO*₂ products. In Figure [7](#page-12-0) we show five snapshots from different regions of the global ocean (Movie S1). The 8D estimates are able to represent a lot

Figure 5. Comparison of the observed *f*CO₂ along three selected cruise tracks contained within the SOCAT database (resampled to 8D; black lines) with the estimated *f*CO₂ from the 8D test-subset (i.e., unseen by the model; blue lines). The blue envelope shows the scaled ensemble standard deviation (5.7 $\sigma_{\rm ens}$). (a) Locations of the cruise tracks with the colors indicating the measured *f*CO₂. The gray region indicates the coastal mask used in this study from Resplandy et al. [\(2024](#page-25-0)). (b) Transect from Japan to New York occupied between 15 Jan 2008 and 11 Feb 2008 (SOCAT cruise: 49P120080116, investigator: Nojiri, Y). (c) Transect from New Zealand to Los Angeles occupied between 13 Nov 2014 and 26 Nov 2014 (SOCAT cruise: AG5W20141113, investigators: Cosca, C., Feely, R., Alin, S.). (d) Transect between Southampton and Punta Arenas occupied between 1 Dec 2018 and 31 Dec 2018 as part of the Atlantic Meridional Transect program (SOCAT cruise: 58US20181201, investigator: Fransson, A). The distance along the *x*-axes of the cruise tracks (b, c, d) is plotted with zero being the westernmost point, regardless of the actual direction of travel. Gray bars along the *x*‐axis indicate where cruise tracks are in the coastal area shown in (a).

of fine-scale spatial variability in *f*CO₂ that could not be seen so far in the 1M products. For example, the 8D estimates depict important *f*CO₂ details in the eastern boundary upwelling regions off northwestern Africa (Figure [7a](#page-12-0)) and off the U.S. West Coast (Figure [7b](#page-12-0)). Of special note are the high *f*CO₂ values tagging the coasts, reflecting recently upwelled waters, and the rapid offshore decrease of *fCO*₂ primarily due to strong biological drawdown. In addition, the filamentous features of these low *fCO*₂ waters are clearly visible. These structures correspond very well to detailed regional observations and modeling studies (Friederich et al., [2002](#page-23-0); Lachkar & Gruber, [2013](#page-24-0); Turi et al., [2014](#page-25-0)).

Similarly, off the West coast of Central America, the 8D estimates reveal the spatial extent of the upwelling‐ driven maxima in *f*CO₂ downstream of the Papagayo and Tehuantepec gaps (Figure [7c\)](#page-12-0). Despite the ephemeral nature of these gap winds, which last for hours to several days (Liang et al., [2009;](#page-24-0) Romero‐Centeno et al., [2003](#page-25-0)), their oceanic signatures persist long enough to be picked up well by our 8 daily product. The spatial structure of these mountain gap wind features in $fCO₂$ is consistent with what is known from in-situ observations (see comparison to the cruise data above (Figure 5a) and the work by for example, Chapa-Balcorta et al. ([2015\)](#page-22-0). Still, the spatial mismatches we identified in comparison with the cruise-line data suggest that the 8‐day resolution is not entirely sufficient to fully capture these ephemeral events.

The high spatial resolution also can resolve the very dynamic structure of $fCO₂$ in the Malvinas Current region (Figure [7d\)](#page-12-0). In this region, strong biological productivity on the Patagonian shelf interacts in a complex manner with the mixing of very different waters masses, that is, the mixing of the warm southward-flowing Brazil Current (BC) and the cold northward flowing Malvinas Current (MC) (Arruda et al., [2015\)](#page-22-0). The meandering features have been seen in modeling studies (Arruda et al., [2015\)](#page-22-0) and the strong gradients created by the mixing are also regularly captured in the raw SOCAT cruise data (see also Figure 5d).

Global Biogeochemical Cycles 10.1029/2024GB008127

Figure 6. Comparison of the OceanSODA‐ETHZv2 estimated *fCO*₂ with observations from 4 open ocean and 1 coastal mooring stations. (a) Map of the long‐term mean *f*CO2 with the location of the mooring sites. (b) Comparison at the PAPA mooring site in the Subarctic Pacific. (c) Comparison at the CCE1 coastal site in the California Current System. (d) Comparison at the TOA site within the central tropical Pacific. (e) Comparison at the SOFS site south of Tasmania. (f) Comparison at the STRATUS mooring site off the coast of Chile. Blue lines show the "unseen" test-subset of estimated Δ*f*CO₂, with the blue envelope showing the scaled ensemble standard deviation $(5.7\sigma_{ens})$. Black lines show the measured mooring data resampled to a daily resolution. Model metrics are shown in gray in the bottom of each plot. Note that these estimates are not used to train the model.

And finally, in the equatorial Pacific, the 8D *f*CO₂ product begins to resolve the tropical instability waves (Figure [7e\)](#page-12-0). However, their shapes are slightly distorted and overly smoothed, which is expected given their rapid propagation speeds (Legeckis, [1977](#page-24-0)). This mismatch has already been seen in the cruise‐line data (see also Figure [5c\)](#page-10-0) and also the mooring data from the TAO125W site (Figure 6d).

4.2. Comparison With Other *f***CO2 Products**

The improvement of the 8D fCO_2 estimates is also evident when comparing it to several other fCO_2 -products (Figure [8\)](#page-13-0), namely, CMEMS‐LSCE (1M by 0.25° Chau et al., [2024\)](#page-22-0), ULB‐MPI‐SOMFFN (1M by 0.25° Roo-baert et al., [2023](#page-25-0)), Jena-CarboScope by (daily by 2.0° Rödenbeck et al., [2014](#page-25-0)), MPI-SOMFFN by (1M by 1° Landschützer et al., [2016](#page-24-0)), and LDEO-HPD by (1M by 1° Bennington et al., [2022](#page-22-0)). Apparent in the comparison is that the fine‐scale gradients of the 8D OceanSODA‐ETHZv2 estimates are sharper compared to the other approaches. In this scenario, we find that the mean gradients $(\sqrt{\sqrt{r}C_2})$ of OceanSODA-ETHZv2 *f*CO₂ are 60% stronger than the other two high-resolution products (Figures [8b](#page-13-0) and [8c](#page-13-0)), and more than three times those of the monthly by $1^{\circ} \times 1^{\circ}$ resolution products (Figures [8e](#page-13-0) and [8f](#page-13-0)). The gradient increases to 0.41 µatm km⁻¹ when considering the 95th percentile (representing dynamic regions) or ∼8 μatm over 20 km, thus approaching the sharp gradients recorded in observational studies (i.e., ~10 μatm over 20 km Sutton et al., [2021\)](#page-25-0).

Global Biogeochemical Cycles 10.1029/2024GB008127

Figure 7. *f*CO₂ for different regions with the period represented shown by the date in brackets. (a) Northwest African coastline, (b) The Northwest coastline of the USA, with eastern boundary upwelling occurring in (a) and (b). (c) The West coast of Central America where the Tehuano gap winds, and Papagayo Jet winds occur, leaving the imprint of the Costa Rica Dome, (d) the Malvinas (Falkland) current off the southeast coast of Argentina, (e) the equatorial Pacific from 165°W to 75°W.

In summary, our method succeeds in capturing fine-scale spatial variability of $fCO₂$ in regions where gradients in driver variables are strong. At the same time, there are still high-frequency features (e.g., tropical instability waves, coastal dynamics) that are not well captured, even at the 8D resolution. However, our method is capable of capturing realistic variability that other methods tend to underestimate.

5. Variability of the Ocean Carbon Sink

5.1. Mean, Trend, and Variability of *F***CO2**

The globally integrated sea-air CO₂ flux *FCO*₂ inferred from the OceanSODA-ETHZv2 product decreases (but increases in strength) from −1.5 PgC yr^{−1} in 1990 to −2.3 PgC yr^{−1} in 2019, with a mean uptake of −1.92 PgC yr⁻¹ over the 1990 through 2019 period. This *F*CO₂ estimate falls within the 1σ-bounds of the SeaFlux ensemble of six *f*CO₂-products of −1.92 ± 0.20 PgC yr⁻¹ calculated with ERA5 winds (Table 4 in Fay et al., [2021\)](#page-23-0). Accounting for the outgassing of natural carbon associated with the balance between river input and burial, that is, the so-called steady-state river outgassing flux of about 0.65 PgC yr^{−1} (Regnier et al., [2022](#page-25-0)), the OceanSODA-ETHZv2 product implies a total sink for anthropogenic CO₂ of -2.33 PgC yr⁻¹ for 1990–1999, of -2.52 PgC yr⁻¹ for 2000–2009, and of −2.85 PgC yr⁻¹ for 2010–2019. This is at the lower end of the uptake estimates summarized by (Gruber et al., [2023\)](#page-23-0) for the three decades using observations, but is higher than most ocean biogeochemical models suggest (Hauck et al., [2020](#page-23-0)). Concerning the $FCO₂$ trend, OceanSODA-ETHZv2 esti-mates −0.26 PgC yr⁻¹ decade⁻¹ over the period 1990–2019 (Figure [9a](#page-14-0)). For the period used in RECCAP2 (2001– 2018; DeVries et al., [2023\)](#page-23-0), we estimate and FCO_2 trend of -0.33 PgC yr⁻¹ decade⁻¹, which is lower than the RECCAP2 ensemble of *f*CO₂-products (−0.61 ± 0.12 PgC yr^{−1} decade^{−1}), but nearly the same as the trend for the RECCAP2 biogeochemical model ensemble (-0.34 ± 0.06 PgC yr⁻¹ decade⁻¹). Concretely, our approach, while

Global Biogeochemical Cycles 10.1029/2024GB008127

Figure 8. A comparison of fCO_2 from different mapping products around Southern Africa, which includes the Agulhas Current and Benguela upwelling system. (a) OceanSODA‐ETHZv2 (this study) for the 8‐day period 17–24 January 2014 (8‐ day by 0.25°). (b) CMEMS-LSCE (monthly by 0.25°) by Chau et al. [\(2024](#page-22-0)), (c) ULB-MPI-SOMFFN (monthly by 0.25° , coastal only) by Roobaert et al. [\(2023](#page-25-0)), (d) Jena‐CarboScope (daily by 2°) by Rödenbeck et al. ([2022](#page-25-0)), (e) MPI‐SOMFFN (monthly by 1°) by Landschützer et al. [\(2016\)](#page-24-0), and (e) LDEO-HPD (monthly by 1°) by Bennington et al. [\(2022](#page-22-0)). The metric ∇ represents the average horizontal gradient of *f*CO2 for the plotted region and ∇*q95* represents its 95th percentile.

on the conservative side, is consistent with the current best estimates of the magnitude and change of the ocean carbon sink (DeVries et al., [2023;](#page-23-0) Gruber et al., [2023](#page-23-0)).

The globally integrated flux varies substantially around these mean uptakes, with the seasonal cycle contributing the most variance (Figure [9b\)](#page-14-0). There is also evidence of an increase in the magnitude of the seasonal cycle over time, confirming previous findings based on theory, models, and observations (Landschützer et al., [2018;](#page-24-0) Rodgers et al., [2023](#page-25-0)). In addition, clear subseasonal variations are visible in the global time series, as well as interannual to decadal variations. Compared to other gap filled *fCO*₂ products (DeVries et al., [2023](#page-23-0)), the interannual to decadal variability of the OceanSODA-ETHZv2-based flux estimate tends to be on the lower end of the spectrum. Still, it shows a clear stalling of the trend toward stronger uptake in the 1990s, and an acceleration thereafter (DeVries et al., [2019;](#page-23-0) Gruber, Clement, et al., [2019;](#page-23-0) Gruber et al., [2023;](#page-23-0) Landschützer et al., [2015](#page-24-0)).

To assess the impact of higher resolution on our estimates of the variability of the ocean carbon sink, we contrast our 8D estimate with a monthly by $1^{\circ} \times 1^{\circ}$ (1M) estimate we obtain by averaging *f*CO₂ from OceanSODA-ETHZv2 and all other inputs to Equation [3](#page-6-0) to 1M (Figure [9a\)](#page-14-0). Although the 1M results are based on the averages of the 8D estimates, the global fluxes of the two products are not identical on longer timescales, that is, the 1M product has a marginally smaller mean (1990–2019) uptake of −1.87 PgC yr^{−1}. This small difference is likely due to small covariances between wind and $\Delta fCO₂$, whose magnitude is scale-dependent (see below). As expected, much larger differences occur on subseasonal timescales, where the 8D product reveals higher crests and deeper troughs than the 1M product. This results in higher temporal variance, which is best analyzed spatially.

The map of the total standard deviation of the sea-air $CO₂$ flux $FCO₂$ reveals strong spatial differences ranging from near zero to more than 7 mmol m^{-2} day⁻¹ (Figure [9b\)](#page-14-0). The northern mid-to high-latitudes have the highest variability (>5 mmol m⁻² day⁻¹), particularly in the Pacific basin. Some island and coastal regions (e.g., the Kerguélen Plateau and Oman upwelling regions) have similarly high variability. The low-latitude regions have

Figure 9. Analysis of the OceanSODA-ETHZv2 sea-air $CO₂$ fluxes ($FCO₂$) (negative means ocean uptake). (a) Map of the global long-term mean sea-air $CO₂$ flux density (1982–2022). The color bars on either side of the figure show different units as indicated. (b) Time series of the globally integrated sea-air CO₂ fluxes (*FCO₂*) for 8-day (8D, blue) and monthly (1M, yellow) estimates, where the latter is calculated by resampling the inputs of Equation [3](#page-6-0) to a lower monthly $\times 1.0^\circ$ resolution and then calculating FCO_2 . (c) The standard deviation (σ) of FCO_2 for the 8D estimates. (d) The difference between (c) and the resampled 1M (monthly \times 1.0° resolution).

low variability (<1 mmol m⁻² day⁻¹), except for the central and eastern tropical Pacific. In the global mean, the temporal standard deviation of the 8D product amounts to $\overline{\sigma} = 2.45$ mmol m⁻² day⁻¹. This is about 10% more than the global mean temporal standard deviation $\bar{\sigma}$ of the 1M product (2.20 mmol m⁻² day⁻¹).

Although the global increase in the captured variability of the 8D product is modest, regionally, the increase in the variability of the sea-air $CO₂$ fluxes can be much more pronounced (Figure 9c). The increase in variability is most notable along a band (∼40°S) in the Sub‐Antarctic Zone (SAZ) in the Southern Ocean, where the 8D product increases the variability relative to the 1M product by more than 50% in some parts. This corresponds well with the results from (Monteiro et al., [2015\)](#page-24-0). The northern high-latitude Atlantic Ocean exhibits a particularly large increase in variability (\gtrsim 1.5 mmol m⁻² day⁻¹). However, the relative increase is smaller compared to the SAZ (<40%).

5.2. Temporal Decomposition of Variability of *F***CO2**

As seen already in the global time series, the total variability of $FCO₂$ is dominated by the seasonal mode (10b), that is, by variability on timescales between 3 and 15 months. The standard deviation of the flux on this timescale goes up to more than 6 mmol m^{-2} day⁻¹, with the highest values found in the North Pacific. In contrast, in the tropics, variability on seasonal timescales is very low. Globally, the standard deviation on seasonal timescales

Figure 10. Maps of the standard deviation of the seasonal (a), subseasonal (b), and interannual (c) components of $FCO₂$ from the 8D product of OceanSODA‐ETHZv2. Values on the plots show the area weighted mean of the variance in $(mmol\ m^{-2} day^{-1})^2$. See Tables S3, S4, and S5 in Supporting Information S1 for low and high-resolution variance, standard deviation, and percentages, respectively.

amounts to $\sigma = 2.61$ mmol m⁻² day⁻¹. The difference between $\sigma(1M)$ and σ (8D) is small (0.03 mmol m^{-2} day⁻¹), indicating that, on seasonal scales, monthly data capture most of the variability.

The subseasonal mode (\leq 3 months) is the next largest contributor to $FCO₂$ variability ($\sigma = 1.24$ mmol m⁻² day⁻¹, Figure 10a). The contribution to variability on these shorter timescales is dominated by the mid-latitudes and the equatorial Pacific, with some regions exceeding 2.5 mmol m^{-2} day⁻¹. To first order, the spatial distribution of the subseasonal variability is similar to that of the seasonal variability (Pearson $R = \sim 0.69$). An important difference is the strong subseasonal contribution in the Oman upwelling system and in the Coral Sea and Tasman Sea regions east of Australia. As expected, the gain in information by going from 1M to 8D is the largest in this subseasonal mode. Globally, the standard deviation increases from the 1M to the 8D product nearly by a factor of 3 (see Tables S3 and S4 in Supporting Information S1).

Finally, variability on timescales longer than 15 months (interannual mode) contributes the least to the overall standard deviation in our product (Figure 10c). The global mean temporal standard deviation amounts to 0.52 mmol m⁻² day⁻¹, for both the 8D and 1M products. Here, the interannual variability of the equatorial Pacific driven by El‐Niño—Southern Oscillation (ENSO) is the most dominant feature, but also the higher latitudes contribute substantially, with several regions having standard deviations of more than 0.8 mmol m⁻² day⁻¹.

This attribution of the total variability of the sea-air $CO₂$ fluxes to three different modes of variability is qualitatively similar to that undertaken by (Gu et al., [2023](#page-23-0)). Perhaps unsurprisingly, there is good agreement between our studies with regard to the partitioning into subseasonal, seasonal, and interannual modes of variability. They found that the total energy of the seasonal variance was an order of magnitude greater than for the subseasonal and interannual modes. This aligns with our findings, where we find an even stronger relative contribution of the subseasonal mode to the total variance, particularly at the 1M resolution.

5.3. Drivers of the Variability of *F***CO2**

The Reynolds decomposition of the sea-air $CO₂$ fluxes (Equation [6](#page-6-0)) permits us to identify the main drivers for each mode of variability (Figure [11](#page-16-0)). The results of the 8D product reveal that all components contribute to the variability, but with very different magnitudes for the different timescales. Changes in ΔfCO_2 dominate the seasonal variability of FCO_2 , contributing 97% to the total seasonal variance. This is also the case for the longer modes of variability, with ΔfCO_2 contributing ~60% to both the sub-decadal and decadal modes of variability. In contrast, for the subseasonal variability, the changes in ΔfCO_2 are less important, but still contribute by more than 20% to the variance.

Wind variability, which is captured in our analysis by the variations in the gas transfer coefficient, dominates the variability on subseasonal timescales, where it contributes more than 80% to the variance. Wind is also very important on sub-decadal timescales, where its contribution is more than 40%. In contrast, it matters much less on decadal and seasonal timescales. The role of the cross‐term contributions is similar to that of the wind variability, with the largest contribution occurring on subseasonal and subdecadal timescales (around 40%), while its contribution to the other timescales is less than 10%.

The covariances between the different Reynolds terms (see Equation [7\)](#page-7-0) are negative, thus contributing negatively to overall variability. This is a result of negative correlations between the mean state and the variability, such as

Figure 11. The contribution of Δ*f*CO′ ² (dark shading), wind and temperature $(k'_x$, medium shading), and the cross-term $(\Delta f \text{CO}_2' \cdot k'_x)$, light shading) to each temporal mode of variability for 8-day (blue) and monthly (yellow) *FCO*₂. The covariances are shown in light gray. The height of the bars (positive only) shows the total standard deviation (σ) and the black numbers above each bar show the total variance (σ^2) . The total height of the bar (positive and negative) represents the sum of the variances without the covariance term. The percentage contributions of k'_x , $\Delta f \text{CO}_2'$, cross-term, and covariances are with respect to the total variance. Thus, multiplying σ^2 with the percentage is approximately the variance for that component (within the uncertainty of rounding). See Tables S3, S4, and S5 in Supporting Information S1 for low and high-resolution variance, standard deviation, and percentages, respectively.

occurs, for example, when regions/times with high mean wind speeds have low variations in the sea-air difference in *f*CO₂. This offsetting effect is particularly strong on seasonal and subseasonal timescales, where it offsets the variability by more than 20%, and nearly 50%, respectively.

Figure 11 also quantifies the strong increase in resolved subseasonal variability when moving from the 1M to the 8D product of OceanSODA‐ ETHZv2. The changes in variance on the other timescales are negligibly small. This indicates that as the time scales get longer, the scales of spatial variability get larger as well, so that one does not gain much in going from 1° to 0.25° resolution when one is interested in the seasonal cycle or longer timescale variability.

The more than 6-fold gain in the subseasonal variance of $FCO₂$ is driven by all components of the Reynolds decomposition (see also Table S5). The greatest gain comes from better‐resolved wind variability as expressed in the contribution of k'_x , whose σ increases nearly three times from 0.40 mmol m⁻² day⁻¹ to 1.12 mmol m⁻² day⁻¹ (1M to 8D). The σ of the cross‐term variability of the subseasonal mode also increases substantially from 0.32 mmol m⁻² day⁻¹ to 0.82 mmol m⁻² day⁻¹. This indicates an increase in the interaction between the variability of k_x and fCO_2 in the highresolution fluxes. Mechanistically this makes sense, since wind‐driven upwelling (captured by k_x) can lead to rapid changes in ΔfCO_2 , thus resulting in larger FCO_2 . The contribution of the ΔfCO_2 term is less important than that of

the wind-driven components, but it still pushes up the variability by 0.48 mmol m⁻² day⁻¹ (Table S5 in Supporting Information S1). Particularly striking is also the very strong negative contribution of the covariance term, which reduces the overall variability by around 50%.

The strong increases in the covariance and cross-term components indicate where, perhaps, the biggest benefit is obtained by going from 1M to 8D resolution. These increases suggest that the higher resolution in time and space improves our capability of capturing the covariability of wind, surface ocean dynamics, and the ocean carbon cycle. This covariability is the result of tight process-based interactions between these drivers, providing much insight into the functioning of the ocean carbon sink (Toolsee et al., [2024\)](#page-25-0). Thus, while the direct contribution of the increase in resolution in Δ*f*CO₂ may not seem particularly large at first sight in Figure 11, it brings a lot of knowledge gain by better capturing the processes controlling the sea-air $CO₂$ flux.

Our results of the Reynold decomposition for the seasonal and longer timescales are similar to those of Gu et al. ([2023\)](#page-23-0). The main consistency is that, on seasonal timescales, variations in k_x , that is, wind dominate, while at longer timescales, the Δ*f*CO₂ term dominates. More specifically, Gu et al. [\(2023](#page-23-0)) attributed 66% of subseasonal variability (\lt 3 months) to the wind component, while we attribute 71% at the 1M-scale (comparable to their study).

6. Case Study: Hurricane Maria

The gain in knowledge that stems from the co-analysis of wind variations with changes in surface ocean biogeochemistry and hence surface ocean *f*CO₂ is best shown through an example, for which we use Hurricane Maria as a case study. Hurricane Maria occurred in September 2017 and belongs to the 10 most intense Atlantic hurricanes ever recorded. It made history as it made its first landfall in Puerto Rico before it turned northward and plowed through the northwestern North Atlantic. Hurricane Maria was most intense from the 17th to 27th of September, maintaining hurricane status throughout this period (shown by the black contours in Figures [12a–](#page-17-0) [12c](#page-17-0)). Thereafter, the system moved eastward. Here, we investigate the local‐scale impacts of the increase in variance by assessing the *FCO*₂ during the passage of Maria, which represents a short-lasting extreme event that is missed in monthly reconstructions.

At first glance, the spatial distribution of the September 2017 mean of the 8D and 1M *FCO*₂ look similar (Figures [12a](#page-17-0) and [12b](#page-17-0)). However, the difference between the two mean states (Figure [12c\)](#page-17-0) shows that outgassing was in fact less intense along the northern part of the hurricane path for the 8D *FCO*₂ relative to 1M. To better

Global Biogeochemical Cycles 10.1029/2024GB008127

Figure 12. The mean of the 8-day (a) and monthly (by) *FCO*, for September 2017. The contour line shows the path of Hurricane Maria from 17th to 27th September, where hourly winds exceeded 20 m s−1 (c) the difference between the 8-day mean and monthly values. (d) a bar plot of *FCO*, for the four time steps in September 2017 for the location indicated by the circle in the maps (a–c). (e) and (f) represent the same, but for $ΔfCO₂$ and k_w respectively. The *FCO*₂ shown in (d) can be thought of as the product of the corresponding bars in (e) and (f) which are scaled by the solubility (not shown). Slight differences between averages (horizontal lines in e,f) are due to the marker not being at exactly the same location for high and low‐resolution estimates.

understand the lower-than-expected outgassing, we plot the temporal evolution of the fluxes, ΔfCO_2 and k_w at a point location (29°N, 72°W) for each of the 8‐day time steps in September 2017 (Figures 12d–12f). The location exhibits one of the strongest differences between the 8D and 1M *FCO*₂ for the spatio-temporal domain.

Importantly, we can also show that the response in Figure 12 is not just due to the intensification of the wind, but also due to changes in fCO_2 (Figures 12e and 12f). Our method is able to capture a decrease in ΔfCO_2 from the period centered on the seventeenth to the following period on the 25th of September, particularly between ∼25°N to ∼30°N (Figure 13c). The decrease (>l15| μatm) co-occurs with a reduction in sea surface temperature and an increase in chlorophyll-a (Figure 13a,b), a relationship which has been previously observed (Babin et al., [2004](#page-22-0); Reul et al., [2021\)](#page-25-0). Mechanistically, the decrease in *f*CO₂ is consistent with previous studies that found tropical cyclones to cool the surface ocean (decreasing *fCO*₂), but also to induce mixing that entrains carbon-rich waters, thus increasing *f*CO₂ (Yu et al., [2020\)](#page-26-0). This is followed by an increase in primary productivity (i.e., a reduction in

Difference between time steps: $(2017-09-25 \pm 4) - (2017-09-17 \pm 4)$

*f*CO₂ Babin et al., [2004](#page-22-0); Lévy et al., [2012;](#page-24-0) Yu et al., [2020](#page-26-0)). For our point location, SST decreased by 2.6°C between the two periods (Figure [12a](#page-17-0)), which would lead to a reduction in *f*CO₂ of ∼42 μatm. However, the OceanSODA-ETHZv2 product predicts a *f*CO₂ reduction of 24 μatm, leaving an excess of 18 μatm, which we attribute to the entrainment of DIC‐rich waters. However, an increase in chlorophyll‐a would result in a further decrease in *f*CO₂, meaning that the contribution of entrainment could be even larger; however, this contribution cannot be empirically determined.

Although OceanSODA-ETHZv2 captures the impacts of Hurricane Maria on *FCO*₂ and *fCO*₂, the magnitude of the event is probably underestimated. For example, observation-based studies found that high-velocity winds increased outgassing by >30 mmol m⁻² day⁻¹ for ~24 hr (Ye et al., [2020;](#page-26-0) Yu et al., [2020](#page-26-0)), compared to the 2 mmol m⁻² day⁻¹ increase observed from 9 to 17 September (Figure [12d](#page-17-0)). The 8D resolution averages the shortlasting spikes (∼24 hr). Furthermore, satellite and reanalysis products may underestimate the spikes; for example, ERA5 underestimates extreme wind conditions by between 5% and 10% (relative to satellites Campos et al., [2022](#page-22-0)). Future work could address this by investigating the influence of using 8‐day Δ*f*CO2 with hourly, daily, 8-day and monthly k_w using an extreme wind speed specific wind speed data set (e.g., [https://www.](https://www.maxss.org) [maxss.org\)](https://www.maxss.org).

7. Discussion

We provide here for the first time a global-scale gap filled $fCO₂$ product at an 8 days and $0.25^\circ \times 0.25^\circ$ resolution, from which we can compute the sea-air $CO₂$ fluxes at the same unprecedented resolution. But what are we gaining from this increase in resolution in terms of quality and what are we learning from this in terms of processes? Next, we discuss these two questions in turn.

7.1. Impact of High Resolution on *f***CO2 Mapping Uncertainty**

In their work investigating a range of gap filled *fCO*₂ products at 1M resolution, Gregor et al. [\(2019](#page-23-0)) found that all products had very similar RMSD ranging between 15 and 20 μatm. They proposed that this is a methodological wall beyond which it would be difficult to progress. Our question is thus, can higher resolution get us over the wall? In the open ocean, we find little reduction in the uncertainties, that is, the RMSD of our 8D product in the open ocean (∼13 μatm) is similar to that of previous approaches with 1M resolution (Figure [3f](#page-8-0)). In addition, relatively large biases still occur in some poorly sampled regions (Figures [5](#page-10-0) and [6](#page-11-0)). In the coastal ocean there is some gain, with OceanSODA-ETHZv2 having a lower RMSD (25.4 µatm) relative to its predecessor (Ocean-SODA‐ETHZ = 27 µatm), a monthly by 1° *p*CO₂‐product (Gregor & Gruber, [2021](#page-23-0)). An improvement in coastal ocean RMSD was also reported by Chau et al. [\(2024](#page-22-0)) in the CMEMS‐FFNN approach (28.5 μatm to 27.6 μatm) by increasing the spatial resolution from 1° to 0.25° (though not the temporal resolution). The slight reduction in coastal RMSD in both approaches is probably due to the fact that sharper gradients and fine‐scale features are better represented in high-resolution estimates (e.g., Figure [8](#page-13-0)). In other words, there is a better match-up between the gridded *fCO*₂ observations and the gridded predictors, also called the representation uncertainty by (Gregor & Gruber, [2021](#page-23-0)). However, coastal uncertainties remain large and the 8D product struggles to fully capture nearshore dynamics (Tables S3 and S4 in Supporting Information S1).

Thus, while we were able to reduce the random uncertainties of the gap-filled $fCO₂$ product at 8D resolution, this is not a breakthrough. Some further reduction may be achieved by going to even higher resolution, especially in time, as this would permit one to capture the more ephemeral or faster developing features, such as the tropical instability waves and short‐lived upwelling events. The big challenge here is the global‐scale availability of predictor variables. The continuing development of global ocean re-analyses that also increasingly incorporate ocean color (e.g., Green Mercator) or commercial satellite observations at daily and 10 m spatial resolutions (Shutler et al., [2024](#page-25-0)) may soon provide such very high‐frequency predictors.

At the same time, we may be at the limit of the capability of the current generation of gap-filling methods that use simple architectures. With the current architecture, where each sample is independent in space and time, these gap‐filling methods will struggle to solve two problems: (a) the basin‐scale problem, where high accuracy of the inferred *fCO*₂ is absolutely essential for constraining the ocean carbon sink, and (b) a fine-scale problem, where drivers can cause rapid and short spatial-scale variations in *f*CO₂ that need to be tracked with high precision. A potential solution to this problem is to explore the use of machine learning methods that retain information at the basin scale (e.g., exploit temporal evolution or correlation), while considering patterns of local variability (e.g.,

Global Biogeochemical Cycles 10.1029/2024GB008127

 1.0 1.4 Mean absolute difference between 8-daily and upscaled fluxes (mmolC m^{-2} d⁻¹)

Difference (a) scaled by standard deviation of 8-day fluxes (%)

Figure 14. (a) The mean absolute difference (MAD) between FCO_2^8 and FCO_2^9 where the latter is calculated with k_x^8 and $\Delta f CO_2^{\text{1M}}$ upscaled to 8D. Thus, (a) shows the impact of using high-resolution $\Delta f CO_2$, even if a high-resolution gas transfer velocity is used. (b) shows the MAD from (a) scaled to the standard deviation of the high-resolution fluxes (Figure [9b](#page-14-0)). The values in the color bar represent the percentage cover that the histogram bin occupies in (b).

filaments). Machine learning and computer vision techniques that exploit spatio‐temporal features, such as those used in weather-forecasting neural networks (e.g., GraphCast and FourCastNet; Lam et al., [2023;](#page-24-0) Pathak et al., [2022](#page-25-0)) and image‐based generative neural networks (Rombach et al., [2022](#page-25-0)) may offer solutions to this multiscale problem.

7.2. Lessons From High‐Resolution *F***CO2**

Our results show that there are distinct benefits of high-resolution predictions of *f*CO₂ and sea-air CO₂ flux. First, the high-resolution predictions of *fCO*₂ reduce the uncertainty of the estimates relative to past low-resolution estimates in the coastal ocean due to improved match‐ups between the in‐situ target data (i.e., SOCAT) and the remote predictors (Section [7.1](#page-18-0)). In addition, higher resolution captures more variability of $fCO₂$ and sea-air *CO*² fluxes (Figure [11](#page-16-0)). However, we also show that the majority of the gained variability, particularly at the subseasonal scale, is due to an increase in the temporal resolution of wind represented by k_x . Still, we also showed that the higher resolution $fCO₂$ product permits us to better capture the covariability of $fCO₂$ and wind, and hence the interaction between physical forcing and the ocean carbon cycle as shown by in‐situ observations (Toolsee et al., [2024\)](#page-25-0).

Since winds drive the majority of the increase in variability, a key question is whether a similar result can be achieved by "upscaling" the fluxes. The upscaled fluxes $\left(FCO_2^\text{upscaled}\right)$ are calculated using low-resolution fCO_2 and high-resolution k_x . The difference between FCO_2^{8D} and FCO_2^{upscaled} (Figure 14a) quantifies the amount of information missed when relying solely on FCO_2^{upscaled} . In large parts of the ocean, particularly the gyre regions, we find minimal differences between FCO_2^{8D} and FCO_2^{upscaled} (<0.4 mmol m⁻² d⁻¹, as shown in Figure 14a). However, in dynamic regions of the ocean, the differences can be substantial (>1 mmol m⁻² d⁻¹).

Scaling these results by the standard deviation of FCO_2^{8D} indicates the local importance of using the highresolution *FCO₂* (Figure 14b). The Antarctic Circumpolar Current (ACC) is the most striking feature, where significant additional variability is resolved as a result of the high-resolution. Interestingly, this aligns with an observation-based study in the Atlantic sector of the ACC that suggested a 3-daily sampling frequency of *f*CO₂ is required to constrain fluxes to a 10% uncertainty threshold (location indicated by the marker in Figure 14; Monteiro et al., [2015\)](#page-24-0). This also holds true for the eastern boundary upwelling regions, and the continental shelf regions in the high‐latitude Pacific and Atlantic. Thus, it is in regions where there is the combination of high spatio-temporal variability and high wind speeds that drives the large differences between FCO_2^{8D} and *FCO*^{upscaled}. However, it is also important to recognize that more sporadic events, such as Hurricane Maria, are also captured, but they may contribute little to the large‐scale variability due to their short‐lived nature (Lévy et al., [2012\)](#page-24-0). While a step in the right direction, we also have to note that the magnitude of the variability is probably underestimated at the 8‐day resolution, for example, Hurricane Maria (Lévy et al., [2012](#page-24-0); Ye et al., [2020](#page-26-0); Yu et al., [2020](#page-26-0)).

Figure 15. Map of the difference between sea-air CO₂ fluxes computed with *x*CO₂ from NOAA's CarbonTracker v2022 (CT2022) and Marine Boundary Layer (MBL) products. Positive (red) shows regions of increased outgassing (or decreased uptake) and negative values show regions of increased uptake (or decreased outgassing) for the CarbonTracker fluxes. The value, |*x*| *q95* shows the 95 percentile of the absolute value of the differences shown in the figure.

8. Caveats

Despite the increases in local-scale variability, we do not see major differences between the mean sea-air $CO₂$ fluxes at 8-day and monthly resolutions at global and interannual scales (Figures [9a](#page-14-0) and [11](#page-16-0)). Thus, if the aim is to constrain $FCO₂$ at large scales, for example, for the Global Carbon Budget (Friedlingstein et al., [2022\)](#page-23-0), our analysis suggests that there is little reason to use 8‐day by 0.25° estimates. Importantly, increasing the resolution of $FCO₂$ does not solve current unanswered problems and questions. For example, it does not close the growing divide in the global CO_2 uptake between the fCO_2 -products and Global Ocean Biogeochemical Models (GOBMs) over the last decade (2010− 2022) (Hauck et al., [2023\)](#page-23-0). Several studies have suggested that this divergence is a result of the overestimation of decadal variability by the *f*CO₂-products (Gloege et al., [2021;](#page-23-0) Hauck et al., [2023\)](#page-23-0). However, the evidence is not conclusive and it may well be that GOBMs underestimate decadal variability (Mayot et al., 2023). However, the fact remains that fCO_2 -products suffer from observational paucity and sampling biases (Gloege et al., [2021;](#page-23-0) Hauck et al., [2023](#page-23-0); Ritter et al., [2017;](#page-25-0) Rödenbeck et al., 2015), a problem that the high-resolution $FCO₂$ estimates presented here cannot solve.

There are a number of specific caveats and challenges that need to be considered in our novel 8D product. The first concerns the use of the NOAA marine boundary layer product (MBL) for the atmospheric dry air mixing ratio (xCO_2^{mbl}) for the computation of the sea-air CO_2 difference. The second concerns the use of a stacked salinity product in order to produce a high‐resolution product spanning four decades.

While the NOAA xCO_2^{mbl} product resolves the dominant mode of spatial variations (i.e., the latitudinal gradient) in the atmospheric dry air-mixing ratio (Tans & Keeling, [2023](#page-25-0)), it fails to resolve any zonal variations. Palter et al. ([2023\)](#page-24-0) pointed out recently that this neglect may lead to significant uncertainties in the sea-air $CO₂$ fluxes, especially downwind of the major continents where most of the fossil fuel $CO₂$ is being emitted. To investigate the potential impact of our choice to use the MBL product, we computed the sea-air $CO₂$ fluxes instead with the zonally resolved NOAA CarbonTracker product for atmospheric *x*CO^{CT2022}, version CT2022 (Jacobson et al., [2023](#page-24-0)). We used exactly the same procedures to compute the atmospheric *f*CO₂ from the dry air mixing ratio as we used for the MBL product.

The use of CarbonTracker for atmospheric $CO₂$ has little to no impact on the globally integrated sea-air $CO₂$ flux. However, this is not true for its spatial distribution, particularly for regions downwind of industrialized countries with high anthropogenic CO_2 emissions (Figure 15), confirming the results of Palter et al. ([2023\)](#page-24-0). The magnitude of these differences can be up to 5% of the total variability for coastal oceans in the lee of continental emissions. The comparison also reveals substantial reductions in ocean uptake in the North Atlantic and in the Indian Ocean, driven by lower atmospheric *f*CO₂ in the CarbonTracker product. The reduction in the North Atlantic is likely a consequence of the strong ocean uptake flux in this region, which tends to lower atmospheric *f*CO₂, and effect not captured in the zonally averaged MBL product.

Thus, the use of xCO_2^{CT2022} instead of xCO_2^{MBL} in the calculation of FCO_2 can be regionally significant. However, the current CarbonTracker (CT2022) product is available only from 2000 onward (Jacobson et al., [2023\)](#page-24-0). Thus, for this analysis, we continue to use the MBL product. This choice also allows us to remain consistent with nearly all previous work on ocean mapping of surface ocean *f*CO₂. However, in the numerical data set, we provide both sea-air $CO₂$ flux estimates for the post-2000 period. However, we recommend further exploration of the benefits of using spatially better-resolved atmospheric CO₂ products, especially when exploring coastal and/or highresolution fluxes.

The second caveat concerns the difficulties associated with the estimation of $fCO₂$ over a period of four decades, given the limitations in the availability of the predictors of choice (Figure [2\)](#page-4-0). For chlorophyll and sea surface height, this means that climatologies are used for the periods where there is no coverage (prior to 1998 and 1993 respectively). Given that climatologies have smoother fields, the *fCO*₂ estimates reflect these smoother input data. In the case of salinity, three different products are used during the four-decade period (Figure [2](#page-4-0) and Figure S5a in Supporting Information S1).

The difference in variability between salinity products can be large for some regions (e.g., Figure S5e in Supporting Information S1). For most of the open ocean, the difference between the salinity products does not make a significant difference, as salinity is a weak driver of ΔfCO_2 (<l5| μatm PSU⁻¹; Figure S5a in Supporting Information S1). However, in the equatorial Pacific, particularly in the western part of the basin, the sensitivity of ΔfCO_2 to salinity is large (>20 μ atm PSU⁻¹). This means that salinity anomalies typically drive a change of more than ∼10 μatm in the western equatorial Pacific for the SODA v3.4.2 salinity (Figure S5b). For the ESA‐CCI salinity, the salinity climate data record product, salinity drives an average change of ∼6 μatm.

We stress that this only affects the variability of ΔfCO_2 since the mean state is captured by the 8-day climatology of salinity. However, it does mean that variability of *f*CO₂ in the western equatorial Pacific, may be overestimated in the period 1982–1992 (SODA salinity) and underestimated from 1993 to 2009 (CMEMS-Multiobs). This applies particularly to the large‐scale changes in salinity driven by El Niño. While this is a lesser problem for $ΔfCO₂$ predictions, this will have a much stronger influence on machine learning estimates of total alkalinity (e. g., Gregor & Gruber, [2021\)](#page-23-0)

9. Conclusions and Next Steps

In this study, we present the first 8-day by $0.25^\circ \times 0.25^\circ$ estimates of sea-air CO₂ fluxes at a global scale over four decades. The high-resolution OceanSODA‐ETHZv2 *f*CO₂‐product is able to capture significantly more variability in sea-air CO₂ flux, with the majority of the increased variability being driven by higher resolution winds, rather than fCO_2 . However, we also show that high-resolution fCO_2 is important in regions with high variability. This includes short-lived high-intensity events, such as upwelling events and hurricanes. In particular, we also demonstrate that the higher resolution *fCO*₂ product allows us to better analyze the interaction between variations in wind and the ocean carbon cycle, thus improving our understanding of the processes.

Following the approach of (Gregor & Gruber, [2021\)](#page-23-0), the *f*CO₂ estimates from the OceanSODA-ETHZv2 approach can be combined with high‐resolution estimates of total alkalinity to estimate high‐resolution ocean acidification parameters that could be used to better understand ocean acidification extremes, for example, (Burger et al., [2020](#page-22-0); Desmet et al., [2022;](#page-23-0) Gruber et al., [2021\)](#page-23-0). Understanding such extreme events from historical data is important so that the drivers of extremes can be better characterized (Gruber et al., [2021](#page-23-0)). This then also allows us to understand current extreme events, such as the North Atlantic marine heatwave in 2023, that could drive anomalous changes in ocean acidification. This requires near‐real‐time capability of machine learning approaches, which is technically quite feasible. However, the current release cycle of SOCAT means that near-real time estimates would be predicting up to 1.5 years beyond the target data (D. C. Bakker et al., [2016\)](#page-22-0). The impact of predicting beyond the target data needs to be investigated before results can be used.

Another area of improvement lies in the temporal resolution of our sea-air $CO₂$ fluxes. The psuedo-daily estimates of sea-air CO₂ fluxes could quite simply be estimated by upscaling ΔfCO_2 to daily resolution while using daily estimates of k_w . This could be further improved by using daily predictors for those that are available (e.g., SST, and SSH) alongside upscaled predictors for those that are not. However, the gain from 8-day to daily *fCO*₂ at the current spatial resolution (0.25°) is unlikely to be as large as the improvement from monthly to 8‐day (Monteiro et al., [2015\)](#page-24-0).

We also need to improve the way we consider variations in atmospheric $CO₂$ for the estimation of the sea-air $CO₂$ fluxes. While the NOAA MBL product has served the community well, further improvement of our ability to quantify the variations of the ocean carbon sink requires us to move to a product that resolves the meridional and zonal variations in atmospheric $CO₂$. The NOAA CarbonTracker product is a good candidate, but by covering only the period from 2000 onward, its use is currently limited. Extending the NOAA CarbonTracker back in time is highly desirable. Other products may be available and shall be explored as well.

Finally, the field of machine learning is developing at an unprecedented rate. New approaches such as Fourier neural operators used in Nvidia's FourcastNet could be incorporated to better capture fine‐scale variability of *fCO*₂. However, it is unclear if even these approaches would be able to reduce the uncertainties beyond "the wall" that sits between 15 and 20 μatm.

Data Availability Statement

The OceanSODA-ETHZv2 data set of Δ*f*CO₂ and *FCO*₂ produced and used throughout this study (Gregor, Gruber, & Shutler, [2024](#page-23-0)) are available at [https://doi.org/10.5281/zenodo.11206366.](https://doi.org/10.5281/zenodo.11206366) Code to create the data and figures (Gregor, Shutler, & Gruber, [2024\)](#page-23-0) is hosted at <https://doi.org/10.5281/zenodo.11230362>. All data used to create the above‐mentioned data set are at least open‐access under academic license and are listed here. SOCAT v2023 data was downloaded from https://socat.info/socat_files/v2023/SOCATv2023.tsv.zip (D. C. Bakker et al., 2016; D. C. E. Bakker et al., 2023). Sea‐surface temperature is from [https://doi.org/10.48670/moi‐00169](https://doi.org/10.48670/moi-00169) (Good et al., [2020](#page-23-0)). ERA5 data (wind and sea level pressure) are from <https://doi.org/10.24381/cds.adbb2d47> (Hersbach et al., [2020](#page-23-0), [2023\)](#page-23-0). Salinity from 2010 to 2020 is from [https://catalogue.ceda.ac.uk/uuid/](https://catalogue.ceda.ac.uk/uuid/fad2e982a59d44788eda09e3c67ed7d5) [fad2e982a59d44788eda09e3c67ed7d5](https://catalogue.ceda.ac.uk/uuid/fad2e982a59d44788eda09e3c67ed7d5) (Boutin et al., 2021). Salinity and mixed layer depth from SODA v3.4.2 were downloaded from <https://dsrs.atmos.umd.edu/DATA/soda3.4.2/REGRIDED/ocean/> (Carton et al., 2018). Salinity after 2021 was downloaded from https://doi.org/10.48670/moi-00051 (Droghei et al., [2016\)](#page-23-0). Chlorophyll-a data can be found at <https://www.oceancolour.org/> (Sathyendranath et al., [2023\)](#page-25-0). We used the reprocessed sea surface height from [https://doi.org/10.48670/moi‐00148](https://doi.org/10.48670/moi-00148) (see acknowledgments).

We are indebted to the large number of scientists who have measured the surface ocean $fCO₂$ over the past few decades and to the programs and agencies that enabled or funded these observations. We are also very grateful to all those who have assembled and quality‐controlled these observations into readily usable products. A special thanks to the Surface Ocean CO2 Atlas (SOCAT) team under the leadership of Dorothee Bakker. SOCAT is an international effort, endorsed by the International Ocean Carbon Coordination Project (IOCCP), the Surface Ocean Lower Atmosphere Study (SOLAS) and the Integrated Marine Biosphere Research (IMBeR) program, to deliver a uniformly quality-controlled surface ocean CO₂ database. We are also grateful to many other programs that have collected and processed marine observations in the last few decades, enabling the development of novel statistical techniques for interpreting the $CO₂$ observations. The work of LG, JS, and NG was supported by the ESA OceanHealth‐OA project (contract number 4000137603/22/I‐DT). JS has received further support by the ESA MAXSS project (4000132954/20/I‐NB). The Ssalto/Duacs altimeter products were produced and distributed by the Copernicus Marine and Environment Monitoring Service (CMEMS) [\(http://](http://www.marine.copernicus.eu) [www.marine.copernicus.eu\)](http://www.marine.copernicus.eu). We thank Rik Wanninkhof and two additional reviewers for their thorough reviews and their great comments that helped to improve this study. Open access funding provided by Eidgenossische Technische Hochschule Zurich.
