Estimated third metatarsal bending stresses are highly susceptible to variations in bone geometry
Estimated third metatarsal bending stresses are highly susceptible to variations in bone geometry

Abstract

Background: Third metatarsal stress fractures are relatively common during Royal Marines recruit training, however their aetiology is poorly understood. Mathematical modelling of the third metatarsal may aid in understanding risk factors for stress fracture, particularly if the influence of footwear on peak bending stresses can be determined. This study built on previous models of metatarsal bending stress by integrating individual metatarsal geometry and gait data.

Methods: Data from five males with size 11 (UK) feet were acquired. MRI images were digitised to determine cross-sectional bone parameters. Gait variables included vertical ground reaction forces, plantar pressure and foot orientation. The magnitude and location of peak bending stresses were calculated for barefoot running, before standard issue combat boots and trainers were compared.

Findings: Estimated peak compressive, tensile and torsional stresses were greater in combat assault boots than trainers (p<0.05) with medium effect sizes but wide confidence intervals. However, differences in bone geometry between individuals had a much greater influence on estimated peak stresses.

Interpretation: Results suggest that bone geometry has a greater influence on third metatarsal stress fracture risk than footwear. Future bone stress simulations should account for bone geometry. Further development of the model in a variety of participants should proceed to verify these suggestions.

Keywords: Bone; mathematical model; stress fracture; gait; beam theory.

1. Introduction

Third metatarsal stress fractures (MT3SF) are the most common lower limb stress fracture affecting Royal Marines (RM) recruits during training[1], however little is known about the aetiology of this injury. Stress fractures develop where insufficient remodelling occurs in response to damage sustained during repeated submaximal loading. Such damage may occur due to either the characteristics of the applied load (e.g. magnitude, frequency, direction) or the bone’s inability to withstand it (e.g. low
bone strength or quality). In an attempt to better understand both the internal loads experienced by the bone, and ability of that bone to withstand it, it would be beneficial to determine the strain acting on the bone. While direct in vivo measurement techniques could be used to indicate the strain acting on bone for a given activity, they are invasive and have many limitations. An alternative approach is to estimate bone loading using mathematical modelling.

The few previous studies to model bone strain have used laboratory-based techniques to estimate external load characteristics[2], while mechanical tests[3] or scanning techniques[4] have provided estimates of bone geometry and quality. Arangio et al.[4] built upon earlier work focusing specifically on the fifth metatarsal[5], in which beam theory was used to calculate stress acting on slices of a plastic mould of the bone. Gross and Bunch[2] used inverse dynamics and beam theory to estimate sagittal plane bending moments and subsequent bending strain acting on the metatarsals during gait. These authors used reference data for bone characteristics and represented the metatarsals as simple uniform ellipses while only estimating strain at the midpoint of the metatarsal. Despite the important work of Gross & Bunch[2] and Arangio et al.[4], no research has combined individual bone geometry, orientation and external load data to estimate MT3 bone stress during locomotion. The development of such a model of bone loading may significantly advance the understanding of MT3SF aetiology.

Footwear can influence the loading of the forefoot and thus potentially MT3SF risk. At the time of testing RM recruits were issued with a gym trainer (GT), used heavily in the early weeks of training, and a combat assault boot (CAB), phased in for most exercises by week 8 of training. This footwear has been assessed previously in regard to MT3SF aetiology[6], with the authors suggesting the CAB would be expected to cause greater risk of MT3SF than the GT, primarily due to increased forefoot loading. It would be beneficial if a model could be developed to accurately assess loads when running in these different footwear conditions, although an initial barefoot assessment is necessary for development of an accurate model.

Therefore, the aims of this study were to 1) develop a model of the MT3 using accurate, subject-specific anatomical data combined with external loading data and 2) apply the model to the comparison of MT3 loading during running in the GT and
CAB. Stage 1 was the development of a model to estimate bending stress acting on
the MT3 during barefoot running. This model would improve on previous attempts in
the literature through the use of participant-specific bone geometry, plantar loading
and kinematic data for running. Stage 2 was to apply the model to the comparison of
peak bending stresses in the MT3 during running with standard issue GT and CAB.
For Stage 2, it was hypothesised that peak MT3 bending stresses would be greater
in the CAB than the GT.

2. Methods

2.1. Participants

Five male participants (age: mean 18.8 SD 0.83 yrs; mass: mean 79.8 SD 2.28 kg)
from a cohort of undergraduate sports science students volunteered to take part in
the study. All volunteers were heel-toe runners with size 11 (UK) feet, familiar with
wearing and running in military boots through participation in the University Officer
Training Corps. The study was given ethical approval by the Sport and Health
Sciences Ethics Committee with all participants free from contraindications to
undergoing MRI scans.

2.2. MRI data

Cod-liver oil markers provided reference points for identifying the MT3 during MRI
scanning due to their high visibility in images. With the participant lying supine, their
right foot was prepared with cod-liver oil markers[7], secured using masking tape in
the following locations: dorsal aspect of the proximal end of the MT3 (articulation
with the lateral cuneiform); dorsal aspect of the distal end of the MT3 (third
metatarsophalangeal joint); medial aspect of the articulation of the first
metatarsophalangeal joint, lateral aspect of the articulation of the fifth
metatarsophalangeal joint. Marker placement locations were estimated by palpation
of the foot, and verified by subsequent observation of the MRI scans.

After preparation with markers, the participant’s right foot was fixed to a rigid plastic
block with Velcro ties so that the ankle was kept at approximately a 90 degree angle,
and the plantar aspect of the foot was in contact with a surface. The scanned section
was defined with respect to the axes of the foot, using marker reference points. Scans were obtained at 5 mm intervals in three planes relative to the foot: sagittal, transverse and frontal. Sample images are presented in Figure 1.

The following MRI scan sequences were used to obtain images in each plane. For the frontal plane scan a turbo spin echo sequence (echo time 20 ms, repetition time 500 ms, averaged over 4 acquisitions) was used with 0.5 x 0.7 mm in-plane resolution and 16 slices of 3 mm thickness acquired. For the transverse plane a T1 weighted gradient echo sequence was employed (echo time 25 ms, a repetition time 20 ms, averaged over 2 acquisitions) with in-plane resolution of 1.0 x 1.1 mm, and 50 slices of 2.5 mm thickness acquired. For the sagittal scan a turbo spin echo sequence (echo time 20 ms, repetition time 500 ms, averaged over 3 acquisitions) was used with 0.5 x 0.6 mm in-plane resolution and 16 slices of 3 mm thickness acquired.

Frontal plane scans were converted from raw DICOM images to AVI clips using ImageJ software (v. 1.46r, National Institutes of Health, USA). Images were concatenated in sequence (proximal to distal) and converted to an AVI clip before being digitised in AVI Digitiser (RF Spectrum Modelling, UK). AVI Digitiser allows sub-pixel digitising using image interpolation, providing high levels of precision. Ninety-six locations were digitised, 32 of the inner surface of the bone, and 64 of the outer surface. In order to promote even spacing of digitised locations, points were digitised in sequence, as demonstrated by the schematic in Figure 2(A). After digitising, 2D coordinates for each point were exported and used to define 96 irregular triangles (Figure 2(B)) from which the area and cross-sectional moment of inertia of each slice were determined. The area of each triangle was calculated using Heron’s formula and summed to give the cross-sectional area of each slice (CA). The vector length between the centroid of each triangle and the centroid of the slice was used to calculate the moment of inertia about the horizontal ($I_{xx}$) and vertical ($I_{yy}$) axes for each slice.

2.3. Dynamic gait data
The collection of shod gait data has been described previously (Nunns et al., 2012).

The collection of barefoot (BF) data differed only in that a pressure plate sampling at 500 Hz (0.5 m long, 4096 sensors, RSScan, Belgium) was used instead of an in-shoe pressure insole device. In the BF condition, the pressure plate was set above a force plate (AMTI, Watertown, MA, USA) flush within a 9 mm thick EVA runway with a Shore A rating of 40, measured with a durometer (Durotech, model B202, Hampden Test Equipment Ltd., England). Participants performed several habituation trials to allow them to adopt their typical foot strike modality[8]. In the shod conditions, participants ran over the laboratory floor, ensuring their right foot struck the force plate.

Two-dimensional kinematic data were collected using an eight camera system (Vicon Peak, 120 Hz, automatic, optoelectronic system; Peak Performance Technologies, Inc., Englewood, CO) and interpolated to 500 Hz to match loading data. Markers were placed at the following locations in order to determine the three-dimensional orientation of the foot: superior posterior calcaneus; inferior posterior calcaneus; inferior lateral calcaneus; lateral malleolus; dorsal aspect of the proximal end of the MT3; dorsal aspect of the distal end of the MT3; medial aspect of the articulation of the first metatarsophalangeal joint, lateral aspect of the articulation of the fifth metatarsophalangeal joint.

The angle of MT3 inclination indicated by dorsal skin markers was verified against the MRI scan for each individual. The sagittal plane angles provided by the cod-liver oil capsules, the midline of the MT3 shaft and the sole of the foot were measured and compared. The results of this analysis (Table 1) indicate that markers represent the angle of inclination of the MT3 to within an average of 0.04 (SD 3.2 degrees, range 8.2 degrees). For the analysis of shod running, the shoe upper prevented accurate placement of markers. Therefore, using the data from Table 1, the foot angle (determined by skin markers) was corrected using the relevant bone angle for each participant to give MT3 inclination angle.

The external load acting on the MT3 was assumed to be applied beneath the MT3 head. Estimation of vertical load at this location was performed using mask analysis within the Footscan Insole (version 2.39, RSScan, Belgium) or Footscan Gait (version 7, RSScan, Belgium) software respectively. For each participant the sagittal
plane image best showing the plantar surface of the metatarsal heads was digitised
to provide the location of the centre of the MT3 head relative to the cod-liver oil
markers, and the length of the MT3. These markers corresponded to the placement
of foot markers during running data collection. For each trial, the central point of the
mask (area 3.4 cm$^2$) for the MT3 head was placed at the centre of the MT3 head,
using these coordinates. Vertical force data for this mask location were exported
from the pressure software and scaled to vertical force data obtained simultaneously
from the force plate, using peak active force as a reference[9].

2.4. Model development

The model considered the MT3 as a cantilever fixed at the proximal end, with the
distal end being free and point-loaded. For each cross-section of the bone, three
axes originating from its centroid were defined. The x-axis was horizontal, the y-axis
was vertical and the z-axis was parallel to the longitudinal axis of the bone. In a
similar approach to that of Milgrom et al.[3] when modelling the tibia, bending
stresses at the cross-section of the MT3 were calculated relative to the x-axis and
the y-axis. Torsional stress was calculated about the z-axis.

At any cross section of the metatarsal, the bending moment can be determined by
equation 1:

$$M_{be} = F(L - x)$$  \hspace{1cm} \text{Eq. 1}

Where $F$ is the applied force; $L$ is the length of the metatarsal and $x$ is the
perpendicular distance from the section to the point of load application. Tensile
stress, compressive stress and axial stress equations are displayed below:

$$\sigma_{ax} = \frac{F}{A}$$  \hspace{1cm} \text{Eq. 4.3}

$$\sigma_c = \sigma_{ax} + \sigma_{be}$$  \hspace{1cm} \text{Eq. 4.4}

$$\sigma_t = \sigma_{ax} - \sigma_{be}$$  \hspace{1cm} \text{Eq. 4.5}
where $\sigma_{ax}$ is axial stress; $\sigma_c$ is compressive stress; $\sigma_{be}$ is bending stress; $\sigma_t$ is tensile stress; $F$ is the force applied and $A$ is the cross-sectional area of the bone. In order to determine maximal $\sigma_{be}$ the following general equations were used:

\[
\sigma_{be}(aboutxaxis) = \frac{(M_{be} \cdot y)}{I_x} \quad \text{Eq. 4.6}
\]

\[
\sigma_{be}(aboutyaxis) = \frac{(M_{be} \cdot y)}{I_y} \quad \text{Eq. 4.7}
\]

where $y$ is the maximal distance of the cross section from the neutral axis in the relevant direction and $I_x$ or $I_y$ is the area moment of inertia about the neutral axis in the relevant direction. Maximal torsional stress was calculated using the following equation:

\[
\sigma_{tor} = \frac{(M_{be} \cdot R)}{I_z} \quad \text{Eq. 4.8}
\]

where $I_z$ is the polar moment of inertia about the neutral axis, and is the sum of $I_x$ and $I_y$ and $R$ is the radius of the outer surface of the bone. $R$ was the mean of the radial distances of the outer 64 points from the centroid. For each cross-sectional slice of the MT3 of each participant, the use of the equations above provided data for the three stresses $\sigma_{ax}$, $\sigma_t$, and $\sigma_c$. Figure 3 is a mechanical diagram of the model.

For each stress category, the magnitude and location of peak stress was identified. All calculations were performed using custom Matlab scripts (v.2008b, The Mathworks Inc, USA). Peak compressive, tensile and torsional stresses under vertical loading were compared between the CAB and GT conditions using Wilcoxon
tests in SPSS (v.21, IBM, USA) using an alpha level of 0.05. Effect sizes with 95% confidence intervals (95% CI) were calculated (Cohen’s $d$ [10]) with a medium effect size considered to be .50.

3. Results

3.1. Stage 1 results – barefoot running

Table 2 summarises the area and location of the slice of metatarsal with the maximum and minimum cross-sectional areas (CA) in each participant. The location of minimum area was also the location of maximum axial stress. In four cases the minimum area was in the slice adjacent to the distal slice, with participant 4 also having a low CA at a distal location. Mid-point and minimum CA were similar between participants, however large variation was seen in the maximum CA.

The mean magnitude and timing of peak plantar force are included in Table 3, in addition to the times of heel off and peak stress. Heel-off always preceded peak force, with peak stress and peak force occurring at similar times. All timings are presented as % of stance time.

Table 4 shows the mean peak compressive, tensile and torsional stresses, and their locations, for each participant. Table 5 indicates the stress values for the mid-point of the metatarsal.

3.2. Stage 2 results – shod running

Table 6 summarises the peak plantar force beneath the MT3 in each condition, which was greater in the CAB for each recruit ($p<0.05$). All peak stresses were significantly greater in the CAB than the GT, with a medium effect size reported (Table 7), although wide 95% CIs reflect the uncertainty in these effects for all footwear comparisons.

4. Discussion

The present study is the first to incorporate individual geometry and individual kinematic and kinetic data into a model of MT3 loading, therefore providing the opportunity to investigate the influence of variations in these factors on MT3 bending.
stresses during gait. Axial, bending and torsional stresses were estimated along the MT3 of the right foot of five males during running, using a simple model based on beam theory. The model was applied initially during barefoot running, and then when shod in the RM recruit standard issue CAB and GT. In partial support of the hypothesis, it was observed that wearing the CAB resulted in statistically significantly greater estimated stresses than wearing the GT, although the small sample size used to pilot this application of the model led to imprecision in the estimates, as reflected by wide confidence intervals. Variation in the geometric properties of the MT3, even within a sample of individuals with the same foot size, led to much larger variation in estimated peak bending stresses. These findings support the inclusion of individual bone geometry data in future metatarsal simulation models.

4.1. Influence of bone geometry

Examination of the locations of maximum stress and minimum CA highlight the importance of bone geometry, in particular its distribution about the centroid and its position relative to the point of load application in determining its resistance to bending. Although the lowest CA of each metatarsal was at the distal end, peak stresses occurred at much more proximal locations, within the middle five slices of the metatarsal, despite the systematic increase in bending moment with each more proximal slice of the metatarsal. Variations in bone geometry may lead to regions of high stress at certain ‘hot spots’ on the metatarsal. As such, future research should avoid the use of arbitrary bone geometry when estimating bending stresses. This is further supported by the large range of estimated peak stresses determined despite participants having the same shoe size and MT3 lengths within a range of 13 mm.

Peak tensile stresses differed by 19 MPa, equivalent to approximately 1100 µε, in MT3s 2 and 4, which were 3 mm different in length, 10 N in peak force. Such variation of peak stress within a relatively homogeneous group suggests estimations of internal loading may be erroneous without knowledge of MT3 geometry. It should be noted that peak stresses are strongly influenced by the maximum distance of any digitised point from the centroid of the slice. Reliability assessment of the model[11] reports very low variation (CV% below 3.45%) between three repeat analyses of the same participant, suggesting that digitisation reliability was high. Further examination of data could provide mean stresses, or stresses at set azimuthal intervals, which
may be less sensitive to variations in geometry. However, if wishing to estimate peak bending stresses, the current results indicate that the use of reference geometry data (e.g. in [2]) in order to compare between individuals is not supported.

4.2. Influence of footwear

Shod running data indicated greater peak bending and torsional stresses in the CAB compared to the GT ($P<0.05$), although the 95% confidence intervals suggest uncertainty over this effect. While a small and under-powered sample was used to test the application of the model, it is noted that for each individual, stresses were greater in the CAB than the GT. Table 6 also shows consistently greater peak ground reaction forces in the CAB than the GT for all individuals. It is therefore suggested that differences in localised force beneath the MT3 likely explain differences in peak bending and torsional stresses between the two conditions (Table 6). Our research group has previously observed increased forefoot loading in the CAB compared to GT [6]. Sensitivity analysis of the model showed that maximal compressive stress increased by around 0.6 MPa per Newton of added force [11]. This therefore suggests that increased plantar loading, specifically at the forefoot during running in the CAB may lead to the observation of increased MT3 bending stresses. Further investigation of these suggestions in a larger sample is required to determine specific mechanisms for increased stress fracture risk with changes in footwear.

Given the observation that increased external loading beneath that MT3 head increases MT3 bending stress, strategies to reduce MT3 stress fracture risk should look to reduce plantar loading. This variable can be influenced by footwear interventions. Windle et al.[12] observed that cushioning insoles reduced plantar pressures at the heel and forefoot in the RM recruit population. The efficacy of cushioning insoles in reducing metatarsal stress fracture risk in particular is not guaranteed however, as this type of injury was not significantly reduced in the RM recruit population when such insoles were prescribed[13]. This may be because an increase in contact area associated with cushioning insoles will reduce plantar pressure but not necessarily force beneath the metatarsal. A forefoot off-loading device may be more effective in reducing MT3 loads. ‘Rocker-bottom’ soles[14, 15]
and custom orthotics[16] have been shown to reduce forefoot loading in diabetic populations, redistributing plantar loads to other areas of the foot. Research is Needed to investigate the efficacy of such devices when integrated into military footwear, including assessment of whether risk of other injuries is increased by redistribution of load.

Barefoot data reveal that peak force and peak stress occurred at similar times during stance, with both events occurring well after heel off, however this relationship was not present in the shod conditions. Further evidence is required to understand whether footwear can influence the timings of peak stresses at the MT3, particularly if these are associated with increased stress fracture risk. Earlier heel off associated with equinus deformity has been suggested to cause earlier and greater loading of the forefoot, increasing risk of metatarsal stress fracture[17]. The results for barefoot running highlight that peak bending stresses occur subsequent to heel off.

4.3. Limitations

There are several limitations which should be acknowledged when interpreting the findings of this study. First, the model did not take into account surrounding structures, muscular attachment or the plantar fascia. Torsional forces, transmitted due to the relative rotation of the forefoot and rearfoot, were not estimated. Pohl et al.[18] reported up to 10 degrees of coupling between these foot segments during running, which may significantly affect bone loading. Gross & Bunch[2] accounted for the influence of toe forces at the metatarsophalangeal joint, as well as the influence of the plantar attachment of the tibialis posterior. The contribution of the tibialis posterior was estimated in their model[2], with this muscle playing an important role in reducing bending stress acting on the metatarsals[19, 20]. The role of plantar musculature should be considered in future, but in order to achieve meaningful data, the location and transmitted force should be accurately modelled in individual cases. Similarly, the effects of the posteriorly-directed tension caused by the attachment of the plantar fascia to the base of the metatarsal heads should be considered. A model of plantar fascia release by Gefen [21] suggests that the importance of this structure in influencing metatarsal bending moments is significant.

Although the model developed in this study has not been directly validated, the estimated loading values can be compared with those in the literature.
peak compressive stress value reported for barefoot running was 114.43 Pa which, if a Young's modulus of 17 GPa is assumed (as in [2]), yields a peak strain of 6749 µε. Gross & Bunch [2] reported mean peak strain at the MT3 to be 5160 µε, despite reporting greater mean peak plantar force than the present study (200 N compared with 147 N). In vivo second metatarsal strain data have been reported during walking to reach around 2000–2500 µε [20, 22-25]. There are no published data for in vivo MT3 strains during walking or running to which comparison could be made. However, second metatarsal strains have been modelled to be greater than the MT3[2], and the transition from walking to jogging has been shown to double the observed MT2 strains[24]. Therefore in line with the estimations of Gross & Bunch[2] it is feasible that strains in the range of 3500 to 5000 µε could be expected on the shaft of the MT3 depending on running speed, however the upper range is below the predictions of the current model. These predictions need to be verified with future work as it is recognised that simplifications of the current model will lead to overestimation of peak MT3 bending loads. Without suitable detailed information on muscle forces and attachments (for example), integrating further estimations into the model would be inappropriate.

It was assumed that throughout stance the MT3 retained the orientation obtained during MRI scanning, and any rotation of the MT3 relative to the vertical force vector was ignored. This assumption will lead to errors when estimating the vertical and horizontal distances of the cortical wall from the centroid during stance (variable ‘y’ in the stress calculations). Given the elliptical nature of the MT3, rotation out of the assumed position may lead to changes in y of a few mm. For a hypothetical mid-shaft slice with a bending moment of 4.5 N.m (150 N force, 0.03 m moment arm) and an inertial value about the x-axis of 150 mm⁴, a change in y from 3 mm to 4 mm would result in a change in bending stress of 30 MPa. Estimations of peak bending stresses are therefore most applicable to a foot position identical to that in which the MRI scans were taken. To improve this aspect of the model, the axial rotation of the MT3 should be tracked during gait and the relevant rotation of cross-sectional bone coordinates performed. However, technology is not widely available to achieve this goal, as skin mounted markers are not capable of accurately tracking bone rotations deep within the foot.
Horizontal forces were not integrated into the model. There is evidence that horizontal forces may be of importance in the aetiology of MT3SF[4, 6, 26], however effective integration of horizontal loads into the model would require knowledge of the location, magnitude and direction of the resultant horizontal force vector relative to the MT3; estimation of the damping of this force before it reaches the MT3 head; and the relative ab-adduction of the forefoot with regard to the rearfoot. Such considerations could be implemented in future iterations.

Predicted bone strain could be validated in a larger sample using bone-mounted strain gauges either in vivo or in cadaver feet, however this was beyond the scope of the present research study. The application of beam theory has been demonstrated in important previous biomechanical models of long bone bending stresses (e.g.[2,3]). As an alternative, a finite element modelling (FE) approach could implement a mesh analysis technique, such as the one used in Brassey et al.[27] to more accurately determine stress across the entire surface of the bone, accounting for factors such as the curvature of the mid shaft. While potentially more accurate however, FE modelling is computationally more demanding. The present model therefore provides a valuable step towards accurate estimation of metatarsal bending stresses, in lieu of robust studies utilising strain gauge data.

5. Conclusion

This was the first model to utilise both individual geometry and dynamic gait data to estimate third metatarsal axial, bending and torsional stresses when running, and we performed a preliminary test of the model for running barefoot and in standard issue military footwear. Results indicate the importance of plantar loading and, in particular, individual bone geometry in determining the magnitude of peak stresses. The variation in geometry even between a relatively homogenous group of individuals may be the dominant factor in determining whether the levels of stress experienced are potentially damaging. Footwear adaptations which facilitate a reduction in forefoot plantar loading may be effective in reducing damaging loads. However, when comparing data between individuals, inferences about internal metatarsal strain based on external load data may be highly inaccurate unless knowledge of the bone geometry is obtained. The present model provides an
opportunity to estimate MT3 bending stresses with consideration of individual geometry and external loading.

6. Conflict of interest statement.

The authors confirm there is no conflict of interest to declare.

Table 4. The mean (SD) of ten trials of the magnitude and location (mm from the most distal aspect of the 3rd metatarsal head) of peak vertical compressive and tensile stresses and peak torsional stress for the right foot third metatarsal of each participant during barefoot running. Mean (SD) peak stress values for the group are also presented. Tensile stresses are negative.

**Figure captions**

Figure 1. Sample images of the third metatarsal of the right foot of one male participant. Top: frontal plane view of mid-section; middle: transverse (plantar) view; bottom: sagittal plane view, showing cod-liver oil skin markers.

Figure 2. A) Schematic of digitised points. Numbers represent the order in the sequence in which the point was digitised. B) The 96 triangles used in the calculation of cross-sectional area and moment of inertia. For one example triangle, the distance from the slice centroid (circle) to the triangle centroid (dashed circle) is highlighted, as used in the calculation of the cross-sectional moment of inertia.

Figure 3. Schematic showing the inputs and measurements considered in the model. (a) Displays the free-body representation of the third metatarsal, in which the axially-directed dashed line (← →) represents the line of axial stress; $\theta =$ angle of inclination of metatarsal to the ground; $F =$ vertical force obtained from pressure data; $L =$ length of metatarsal; $x =$ perpendicular distance of slice from point of force application; the thick black intersection represents a sample slice taken from the mid-shaft. This slice is depicted from a frontal perspective in (b), where $X =$ Centroid of slice; $R =$ radius of outer surface of metatarsal. The axes about which bending stress moment arms ($y$) and inertial properties are calculated are also identified.
