196 **Abstract**

197 **Aim.** Large tropical trees form the interface between ground and airborne observations,
198 offering a unique opportunity to capture forest properties remotely and to investigate their
199 variations on broad scales. However, despite rapid development of metrics to characterize the
200 forest canopy from remotely sensed data, a gap remains between aerial and field inventories.
201 To close this gap, we propose a new pan-tropical model to predict plot-level forest structure
202 properties and biomass from just the largest trees.

203 **Location.** Pan-tropical

204 **Time period.** Early 21st century

205 **Major taxa studied.** Woody plants

206 **Method.** Using a dataset of 867 plots distributed among 118 sites across the tropics, we tested
207 the prediction of the quadratic mean diameter, basal area, Lorey's height, community wood
208 density and aboveground biomass from the i th largest trees.

209 **Result.** Measuring the largest trees in tropical forests enables unbiased predictions of plot and
210 site-level forest structure. The 20 largest trees per hectare predicted quadratic mean diameter,
211 basal area, Lorey's height and community wood density and aboveground biomass with 12%,
212 16%, 4%, 4% and 17.7% of relative error. Most of the remaining error in biomass prediction is
213 driven by differences in the proportion of total biomass held in medium size trees (50-70 cm),
214 which shows some continental dependency with American tropical forests presenting the
215 highest proportion of total biomass in these intermediate diameter classes relative to other
216 continents.

217 **Conclusion.** Our approach provides new information on tropical forest structure and can be
218 employed to accurately generate field estimates of tropical forest carbon stocks to support the
219 calibration and validation of current and forthcoming space missions. It will reduce the cost of
220 field inventories and contribute to scientific understanding of tropical forest ecosystems and
221 response to climate change.

222 **Introduction**

223 The fundamental ecological function of large trees is well established for tropical forests. They
224 offer shelter to multiple organisms (Remm & Löhmus, 2011; Lindenmayer *et al.*, 2012),
225 regulate forest dynamics, regeneration (Harms *et al.*, 2000; Rutishauser *et al.*, 2010) and total
226 biomass (Stegen *et al.*, 2011), and are important contributors to the global carbon cycle
227 (Meakem *et al.*, 2017). Being major components of the canopy, the largest trees may also
228 suffer more than sub-canopy and understory trees from climate change, as they are directly
229 exposed to variations in solar radiation, wind strength, temperature seasonality and relative air
230 humidity (Laurance *et al.*, 2000; Nepstad *et al.*, 2007; Lindenmayer *et al.*, 2012; Thomas *et al.*,
231 2013; Bennett *et al.*, 2015; Meakem *et al.*, 2017). Because they are visible from the sky, large
232 trees are ideal for monitoring forest responses to climate change via remote sensing (Bennett
233 *et al.*, 2015; Asner *et al.*, 2017).

234 Large trees encompass a disproportionate fraction of total aboveground biomass (AGB) in
235 tropical forests (Chave *et al.*, 2001; Lutz *et al.*, 2018), with some variations in their relative
236 contribution to the total AGB among the tropical regions (Feldpausch *et al.*, 2012). In Central
237 Africa, the largest 5% of trees in a forest sample plot, i.e. the 5% of trees with the largest
238 diameter at 130 cm, store 50% of forest plot aboveground biomass on average (Bastin *et al.*,
239 2015). Consequently, the density of large trees largely explains variation in forest AGB at local
240 (Clark & Clark, 1996), regional (Malhi *et al.*, 2006; Saatchi *et al.*, 2007), and continental scales
241 (Stegen *et al.*, 2011; Slik *et al.*, 2013). Detailing the contribution of each single tree to the
242 diameter structure, we showed previously that plot-level AGB can be predicted from a few
243 large trees (Bastin *et al.*, 2015), with the measurement of the 20 largest trees per hectare being
244 sufficient to estimate plot-level biomass with less than 15% error in reference to ground
245 estimates. These findings suggested that a substantial gain of cost-effectiveness may be
246 achieved by focusing forest inventories on the largest trees rather than all size classes.
247 Similarly, it suggested that remote sensing (RS) approaches could focus on the measurement
248 of the largest trees, instead of properties of the entire forest stand.

249 Several efforts are underway to close the gap between remote sensing of forest biomass and
250 field surveys (Coomes *et al.*, 2017; Jucker *et al.*, 2017). However, existing RS approaches
251 typically require ground measurement of all trees above or equal to 10 cm of diameter (D) for
252 calibration (Asner *et al.*, 2012; Asner & Mascaro, 2014). Collecting such data in the field is
253 costly and time-consuming, which therefore limits the spatial representativeness of available
254 plot networks. Besides, extrapolation methods of ground-based biomass estimations on RS
255 data still faces important limits. For instance, using mean canopy height extracted from active
256 sensors (Mascaro *et al.*, 2011; Ho Tong Minh *et al.*, 2016), or canopy grain derived from optical
257 images (Proisy *et al.*, 2007; Ploton *et al.*, 2012, 2017; Bastin *et al.*, 2014), the biomass is
258 predicted with an error of only 10-20% compared to ground-based estimates. However, this
259 good level of accuracy is limited to the extent of the RS scene used, which considerably
260 decrease in the upscaling step necessary for national or global maps (Xu *et al.*, 2017). A
261 promising development to alleviate this spatial restriction lies in the ‘universal approach’,
262 proposed by Asner *et al.* (2012) and further adapted in Asner and Mascaro (2014), in which
263 plot-level biomass is predicted by a linear combination of ground-based and remotely-sensed
264 metrics. The ‘universal approach’ relies upon canopy height metrics derived from radar or
265 LiDAR (top of canopy height, TCH), and basal area (BA, i.e. the cumulated cross-sectional
266 stems area) and community wood density (i.e. weighted by basal area, WD_{BA}) derived from
267 field inventories. Plot AGB is then predicted as follows (Asner *et al.*, 2012):

$$268 \text{ AGB} = a\text{TCH}^{b1}\text{BA}^{b2}\text{WD}_{BA}^{b3}(1)$$

269 While generally performing better than approaches based solely on remote sensing of tree
270 height (Coomes *et al.*, 2017), this model relies on exhaustive ground measurements (i.e. wood
271 density and basal area of all trees above 10 cm of diameter at 130 cm, neither of which is
272 measured using any existing remotely sensed data).

273 Recent advances in remote sensing allow the identification of single trees in the canopy (Ferraz
274 *et al.*, 2016), estimation of adult mortality rates for canopy tree species (Kellner & Hubbell,
275 2017), description of the forest diameter structure (Stark *et al.*, 2015), depiction of crown and
276 gap shapes (Coomes *et al.*, 2017), and even identification of some functional traits of canopy

277 species (Asner *et al.*, 2017). As routine retrieval of some canopy tree metrics is within reach,
278 we test here the capacity of the largest trees, i.e. trees that can be potentially derived using
279 remote sensing, to predict plot-level biomass. To this end, we adapted equation (1) as follows:

$$280 \text{ AGB} = a(Dg_{LT} H_{LT} WD_{LT})^{b1} \text{ (2)}$$

281 where for the i^{th} largest trees, Dg_{LT} is the quadratic mean diameter, H_{LT} the mean height, and
282 WD_{LT} the mean wood density among the i^{th} largest trees.

283 Using a large database of forest inventories gathered across the tropics (Figure 1), including
284 secondary and old growth forest plots, we test the ability of the largest trees to predict various
285 metrics estimated at 1-ha plot level, namely the mean quadratic diameter, the basal area, the
286 Lorey's height (i.e. plot-average height weighted by basal area), the community wood density
287 (i.e. plot-average wood density weighted by basal area) and mean aboveground live biomass
288 (supplementary figure 1). By testing different numbers of largest trees as predictors, we aim to
289 propose a threshold of the minimal number of largest trees required to predict forest plot
290 metrics at a pan-tropical level with no bias and low uncertainty (i.e. error inferior to 20%). While
291 previous work focused on estimating biomass in Central African forests (Bastin *et al.*, 2015),
292 the present study aims at generalizing the potential of large trees to predict these different plot
293 metrics at continental and pan-tropical scales. Taking advantage of a unique dataset gathered
294 across the tropics (867 1-ha plots), we also investigate major differences in forest structure
295 across the three main tropical regions: the Americas, Africa and Asia. We further discuss how
296 this approach can be used to guide innovative RS techniques and increase the frequency and
297 representativeness of ground data to support global calibration and validation of current and
298 planned space missions. These include the NASA Global Ecosystem Dynamics Investigation
299 (GEDI), NASA-ISRO Synthetic Aperture Radar (NISAR), and ESA P-band radar (BIOMASS)
300 (Le Toan *et al.*, 2011; Dubayah *et al.*, 2014). This study is a step forward in bringing together
301 remote sensing and field sampling techniques for quantification of terrestrial C stocks in tropical
302 forests.

303 **Material & Methods**

304 **Database**

305 For this study, we compiled standard forest inventories conducted in 867 1-ha plots from 118
306 sites across the three tropical regions (Figure 1), including mature and secondary forests. Each
307 site comprises all the plots in a given geographical location, i.e. within a 10 km radius and
308 collected by a Principal Investigator and its team. These consisted of 389 plots in America (69
309 sites), 302 plots in Africa (35 sites) and 176 plots in Asia (14 sites). Data were provided by
310 Principal Investigators (see supplementary Table 1), and through datasets available on the
311 following networks: TEAM (<http://www.teamnetwork.org/>), CTFS (<http://www.forestgeo.si.edu/>;
312 Condit *et al.*, 2012) and ForestPlots (<https://www.forestplots.net/>) for AfriTRON (the African
313 Tropical Rainforest Observation Network; www.afritron.org) and RAINFOR (the Amazon forest
314 inventory network; <http://www.rainfor.org/>) networks.

315 We selected plots located between 23°N and 23°S, including tropical islands, with an area of
316 1-ha to ensure stable intra-sample variance in basal area (Clark & Clark, 2000). Plots in which
317 at least 90% of the stems were identified to species, and in which all stems with the diameter
318 at 130 cm greater than or equal to 10 cm had been measured were included. Wood density,
319 here recorded as the wood dry mass divided by its green volume, was assigned to each tree
320 using the lowest available taxonomic level of botanical identifications (i.e. species or genus)
321 and the corresponding average wood density recorded in the Global Wood Density Database
322 (GWDD, Chave *et al.*, 2009; Zanne *et al.*, 2009). Botanical identification was harmonized
323 through the Taxonomic Names Resolution Service (<http://tnrs.iplantcollaborative.org>), for both
324 plot inventories and the GWDD. For trees not identified to species or genus (~5%), we used
325 plot-average wood density. We estimated heights of all trees using Chave *et al.*'s (2014) pan-
326 tropical diameter-height model which accounts for heterogeneity in the D-H relationship using
327 an environmental proxy:

$$328 \ln(H) = 0.893 - E + 0.760 \ln(D) - 0.0340 \ln(D)^2 \quad (3)$$

329 Where D is the diameter at 130 cm and E is a measure of environmental stress (Chave *et al.*,
330 2014). For sites with tree height measurements (N=20), we developed local D-H models, using

331 a Michaelis-Menten function (Molto *et al.*, 2014). We used these local models to validate the
 332 predicted Lorey's height (i.e. plot average height weighted by BA) from the largest trees, of
 333 which height has been estimated with a generic H-D model (equation 3, Chave *et al.* 2014).
 334 We estimated plot biomass as the sum of the biomass of live tree with diameter at 130 cm
 335 superior or equal to 10 cm, using the following pan-tropical allometric model (Réjou-Méchain
 336 *et al.*, 2017):

$$337 \text{ AGB} = \exp(-2.024 - 0.896E + 0.920 \ln(\text{WD}) + 2.795 \ln(D) - 0.0461(\ln(D^2))) \quad (4)$$

338 **Plot-level metric estimation from the largest trees**

339 The relationship between each plot metric, namely basal area (BA), the quadratic mean
 340 diameter (Dg), Lorey's height (H_{BA}; the mean height weighted by the basal area) and the
 341 community wood density (WD_{BA}; the mean wood density weighted by the basal area), and
 342 those derived from largest trees was determined using an iterative procedure following Bastin
 343 *et al.* (2015). Trees were first ranked by decreasing diameter in each plot. An incremental
 344 procedure (i.e. including a new tree at each step) was used to sum or average information of
 345 the *i* largest trees for each plot metric. Each plot-level metric was predicted by the respective
 346 metric derived from the *i*th largest trees. For each increment, the ability (goodness of fit) of the
 347 *i* largest trees to predict a given plot-metric was tested through a linear regression. To avoid
 348 overfitting, a Leave-One-Out procedure was used to develop independent site-specific models
 349 (N=118). Specifically, the model to be tested at a site was developed with data from all other
 350 sites. Errors were then estimated as the relative root mean square error (rRMSE) computed
 351 between observed and predicted values (X):

$$352 \text{ rRMSE} = \sqrt{\sum \frac{(X_{\text{obs}} - X_{\text{pred}})^2}{n}} / \bar{X} \quad (5)$$

353 The form of the regression model (i.e. linear, exponential) was selected to ensure a normal
 354 distribution of the residuals.

355 To estimate plot basal area, we used a simple power-law constrained on the origin, as linear
 356 model resulted in non-normal residuals. Plot-level basal area (BA) was related to the basal
 357 area for the *i* largest trees (BA_{*i*}) using:

358 $BA = b_1 \sum BA_i^{y1} \quad (6)$

359 To estimate the quadratic mean diameter, Lorey's height and the wood density of the
360 community, we used simple linear models relating the plot-level metrics and the value of the
361 metrics for the i largest trees:

362 $D_g = a_2 + b_2 D_{gi} \quad (7)$

363 $H_{BA} = a_3 + b_3 \overline{H_i} \quad (8)$

364 $WD_{BA} = a_4 + b_4 \overline{WD_i} \quad (9)$

365 Both Lorey's height (H_{BA}) and the average height ($\overline{H_i}$) of the i^{th} largest trees depend on the
366 same D-H allometry, which always contains uncertainty whether we use a local, a continental
367 or a pan-tropical model. To test the dependence of the prediction of H_{BA} from $\overline{H_i}$ on the
368 allometric model, we used measurement from Malebo in the Democratic Republic of the
369 Congo, where all heights were measured on the ground (see supplementary figure 2).

370 The quality of the predictions of plot-level metrics from the largest trees is quantified using the
371 relative root mean square error (rRMSE) between measured and predicted values, and
372 displayed along the cumulated number of largest trees. Model coefficients are estimated for
373 each metric derived from the largest trees (N_{LT}) and averaged across the 118 models (see
374 supplementary table 2).

375 Mean rRMSE is plotted as a continuous variable, while its variation is presented as a
376 continuous area between 5th and the 95th percentiles of observed rRMSE.

377 **The optimal number of largest trees for plot-level biomass estimation**

378 The optimal number of largest trees N_{LT} was determined from the prediction of each plot-level
379 metric considered above, i.e. keeping a small number of trees while ensuring a low level of
380 error for each structural parameter. We then predicted plot-level biomass from the N_{LT} model
381 (equation 2). The final error was calculated by propagating the entire set of errors related to
382 equation 4 (Réjou-Méchain *et al.*, 2017) in the N_{LT} model (i.e. error associated to each allometric
383 model used). The model was then cross-validated across all plots (N=867).

384 **Investigating residuals: what the largest trees do not explain**

385 To understand the limits of predicting AGB through N_{LT} , we further investigated the relationship
386 between AGB residuals and key structural and environmental variables using linear modelling.
387 Forest structure was investigated through the total stem density (N), the quadratic mean
388 diameter (Dg), Lorey's height (H_{BA}) and community wood density (WB_{BA}). As environmental
389 data, we used the mean annual rainfall and the mean temperature computed over the last 10
390 years at each site using the Climate Research Unit data (New *et al.*, 1999, 2002), along with
391 rough information on soil types (Carré *et al.*, 2010). Major soil types were computed from the
392 soil classification of the Harmonized World Soil Database into IPCC (intergovernmental panel
393 on climate change) soil classes. In addition, considering observed differences in forest
394 structure across tropical continents (Feldpausch *et al.*, 2011, 2012) and recent results on pan-
395 tropical floristic affinities (Slik *et al.*, 2015), we tested for an effect of continent (America, Africa
396 and Asia) on the AGB residuals. Differences in forest structure and AGB among continents
397 were also illustrated through the analysis of their distribution.

398 The importance of each variable was evaluated by calculating the type II sum of squares that
399 measures the decrease in residual sum of squares due to an added variable once all the other
400 variables have been introduced into the model (Langsrud, 2003). Residuals were investigated
401 at both plot and site levels, the latter analyzed to test for any influence of the diameter structure,
402 which is usually unstable at the plot level due to the dominance of large trees on forest metrics
403 at small scales (Clark & Clark, 2000). Here we use a principal component analysis (PCA) to
404 summarize the information held in the diameter structure by ordinating the sites along the
405 abundance of trees in each diameter class (from 10 to +100 cm by 10 cm bins).

406

407 **Results**

408 **Plot-level metrics**

409 Plot metrics averaged at the site level (867 plots, 118 sites) present important variations within
410 and between continents. In our database, the quadratic mean diameter varies from 15 to 42
411 $\text{cm}^2\text{ha}^{-1}$, the basal area from 2 to 58 m^2ha^{-1} , Lorey's height from 11 to 33 m and the wood
412 density weighted by the basal area from 0.48 to 0.84 gcm^{-3} (supplementary figure 1). Such
413 important differences between minimal and maximal values are observed because our
414 database cover sites with various forest types, from young forest colonizing savannas to old
415 growth forest. However, most of our sites are found in mature forests, as shown by relatively
416 high average and median value of each plot metric (average aboveground biomass = 302
417 Mgha^{-1} ; supplementary figure 1). In general, highest values of aboveground biomass are found
418 in Africa, driven by highest values of basal area and highest estimations of Lorey's height.
419 Highest values of wood density weighted by basal area are found in America.

420 **Plot-level estimation from the *i* largest trees**

421 Overall, plot metrics at 1-ha scale were well predicted by the largest trees, with qualitative
422 agreement among global and continental models (Figure 2). When using the 20 largest trees
423 to predict basal area (BA) and quadratic mean diameter (Dg), the mean rRMSE was < 16%
424 and 12%, respectively (Figs 3a and 3b). Lorey's height (H_{BA}) and wood density weighted by
425 basal area (WD_{BA}) were even better predicted (Figs 3c and 3d), with mean rRMSE of 4% for
426 the 20 largest trees. The prediction of Lorey's height from the largest trees using local
427 diameter-height model (supplementary figure 2a) yielded results similar to those obtained
428 using equation 3 of Chave et al. (2014). More importantly, it also yielded similar results to
429 prediction of Lorey's height from the largest trees using plots where all the trees were
430 measured on the ground (supplementary figure 2b). This suggests that our conclusions are
431 robust to the uncertainty introduced by height-diameter allometric models.

432 **AGB prediction from the largest trees**

433 We selected "20" as the number of largest trees to predict plot metrics. The resulting model
434 predicting AGB (Mgha^{-1}) based on the 20 largest trees is:

435 $AGB = 0.0735 \times (Dg_{20}H_{20}WD_{20})^{1.1332}$ (rRMSE=0.179; R²=0.85; AIC= -260.18) (10)

436 Because the exponent was close to 1, we also developed an alternative and more operationa
437 l model with the exponent constrained to 1, given by:

438 $AGB = 0.195 \times (Dg_{20}H_{20}WD_{20})$ (rRMSE=0.177; R²=0.85; AIC=-195) (11)

439 Ground measurements of plot AGB were predicted by our N_{LT} model with the exponent
440 constrained to 1, with a total error of 17.9% (Figure 4), a value which encompass the error of
441 the N_{LT} model and the error related to the allometric model chosen. The Leave-One-Out cross-
442 validation procedure yielded similar results (rRMSE=0.19; R²=0.81), validating the use of the
443 model on independent sites.

444 **Determining the cause of residual variations**

445 The explanatory variables all together explain about 37% of the variance in AGB both at plot
446 and site levels when omitting the diameter structure, and about 63% at site level when included
447 (Figure 5). In general, forest structure and particularly the stem density explained most of the
448 residuals (table 1; weights: 79% and 54% at plot- and site-level respectively). The stem density
449 was followed by a continental effect (weights: 18%, 28% and 1%, respectively for Africa,
450 America and Asia) and by the effect of H_{BA} and WD_{BA} (respective weights: 1% and 0% at the
451 plot level, 0% and 11% at the site level, and 23% and 0% when accounting for the diameter
452 structure at the site level). Inclusion of the diameter structure provided the best explanation of
453 residuals, with 63% of variance explained, and a weight of 69% for the first axis of the PCA
454 (supplementary figure 3). This first axis of the PCA was related to the general abundance of
455 trees at a site, and in particular medium-sized trees (40-60cm). Among environmental
456 variables, only rainfall was significantly related to the residuals at the site level when the
457 diameter structure was considered (2%).

458 **Differences among continents**

459 While diameter structure explained a large fraction of the residual variance of our global model,
460 there was marked difference in forest structure across continents (Figure 6). Consequently,
461 we investigated differences between continents in the distribution of residuals of the pan-
462 tropical model (Figure 6a), in the relative contribution of the 20 largest trees to plot total

463 biomass (Figure 6b), and in the contribution to the total aboveground biomass per diameter
464 class (Figs. 6c-f). To this end, we considered the following four classes of diameter at 130 cm:
465 10 to 30 cm, 30 to 50 cm, 50 to 70 cm and above 70 cm. Results show that the prediction of
466 biomass from the 20 largest trees using the pan-tropical model tends to be slightly
467 overestimated in Africa (+ 3%) and underestimated in America (- 3%) and in Asia (-5%) (Figure
468 6a). The proportion of biomass is higher in high diameter class (over 70 cm) in Africa, in
469 intermediate diameter classes (between 30 and 70 cm) in America and is equally distributed
470 among the different diameter classes in Asia (Figure 6 c-d).

471 **Discussion**

472 **The largest trees, convergences and divergences between continents**

473 Sampling a few largest trees per hectare generally allows an unbiased prediction of four key
474 descriptors of forest structures across the tropics. There is generally no improvement in
475 predicting biomass, quadratic mean diameter, Lorey's height (H_{BA}) or community wood density
476 beyond the first 10-to-20 largest trees (Figure 2, Figure 3a). But when a forest plot presents
477 an abundant number of large trees (Figure 5d), increasing the number of trees sampled does
478 improve the model's accuracy. This is due to the fact that the higher total AGB in a plot, the
479 lower the proportion of total AGB encompassed by the largest trees. This is particularly true
480 for BA for which rRMSE continues to decrease up to 100 largest trees (Figure 2a). In contrast,
481 Lorey's height predictions are altered when a large number of trees are included (Figure 2c),
482 i.e. when smaller, often suppressed, trees draw the average down (Farrior et al., 2016). This
483 might explain why the prediction of AGB does not mirror that of basal area (Figure 2b, Figure
484 3a), and suggest that the number of largest trees shall be set independently to each predictor
485 considered. Interestingly, the evolution of relative error in AGB prediction as a function of the
486 number of largest trees considered does not follow the same path between continents. For
487 instance, the error of prediction saturates more quickly in Africa and Asia than America.
488 Investigation of residuals showed that the diameter structure (Figure 5c, supplementary Figure
489 3b), and in particular the number of medium size trees (Figure 5d), drives variability in AGB
490 predictions. It is therefore not surprising to see that in our dataset the site with higher levels of
491 underestimations is the one with the highest number of medium size trees, which is found in
492 Asia in the Western Ghats of India.

493 The good performance of models based on the 20 largest trees in predicting Lorey's height
494 and community wood density at site level was not surprising. Both metrics were indeed
495 weighted by basal area, driven de facto by the largest trees. Their consistency across sites
496 and continents was not expected though, which emphasize the generality of our approach.

497 The predictability of plot-level forest structure metrics from the largest trees implies that
498 characteristics of smaller trees do not vary completely independently from those of the larger

499 trees. For example, plots where the largest trees have low basal area tend to have low plot-
500 level basal area (Figure 3a), meaning that the total size of the smaller trees is sufficiently
501 constrained so that it does not compensate for the small size of the largest trees. Such
502 constraints could arise through size-frequency distributions being set by allometric scaling
503 rules (Enquist et al., 2009), or could be due to the largest trees responding in the same way
504 as the remaining smaller trees to environmental drivers.

505 Despite the general consistency of these relationships across continents, slight differences are
506 evident when comparing the pan-tropical model residuals across continents (Figure 6,
507 supplementary figure 4). These differences indicate biogeographic variation in forest structure.
508 In America, our pan-tropical model tends to slightly underestimate basal area (mean: -5%) and
509 overestimate Lorey's height (mean: +3%) (supplementary figure 4). This suggests that large
510 trees make up a smaller proportion of basal area in America and that for a given diameter we
511 find higher trees (supplementary figure 2), the later confirming that the shape of height-
512 diameter allometries varies between continents (Banin et al., 2012; Sullivan et al., 2018). In
513 Africa, large trees (i.e. DBH > 70 cm) are more abundant and account for a large fraction of
514 plot biomass (figure 6f). This supports previous observations that African forests are
515 characterized by fewer but larger stems (Feldpausch *et al.*, 2012; Lewis *et al.*, 2013), while
516 forests in the Americas have more stems but generally have lower biomass (Sullivan et al.,
517 2017). In Asia, the distribution of the biomass across diameter classes appears more balanced
518 (Figure 6c-f). Such differences in forest structure, even if being quite limited, suggest tropical
519 forests differ between continents in terms of dynamics, carbon cycling, response and feedback
520 to climate and resilience to external forcings (e.g. climate change, forest degradation and
521 deforestation).

522 Interestingly, while a recent global phylogenetic classification of tropical forest groups
523 American with African forests vs. Asian forests (Slik et al., 2018), our study of forest structure
524 properties tends more to single out American forests, and particularly highlight the contrast in
525 between African and American forests. Although this deserves further investigations, it might
526 reveal a lack of close relationship between forest structure properties and phylogenetic similarity,

527 which echoes recent results on the absence of relationship between tropical forest diversity
528 and biomass (Sullivan *et al.*, 2017).

529 **Largest trees, a gateway to global monitoring of tropical forests**

530 Revealing the predictive capacity held by the largest trees, our results constitute a major step
531 forward to monitor forest structures and biomass stocks. The largest trees in tropical forests
532 can therefore be used to accurately predict various ground-measured properties (i.e. the
533 quadratic mean diameter, the basal area, Lorey's height and community wood density), while
534 previous work has predicted only biomass "estimates" (e.g. Slik *et al.*, 2013; Bastin *et al.*,
535 2015). Our approach allows us to (i) describe forest structure independently of any biomass
536 allometric model (ii) and integrates environmental-based variations in D-H relationship, known
537 to vary locally (Feldpausch *et al.*, 2011; Kearsley *et al.*, 2013;). It is also (iii) relatively
538 insensitive to differences in floristic composition and community wood density (Poorter *et al.*,
539 2015).

540 Furthermore, the "largest trees" models were developed for each plot-level metric and for any
541 number of largest trees. Thus, they do not rely on any arbitrary threshold of tree diameter. Note
542 that the optimal number of largest trees to be measured (i.e. 20) was set for demonstration
543 and can vary depending on the needs and capacities of each country or project (see
544 supplementary table 2). In the same way, local models could integrate locally-developed
545 biomass models, when available. Consequently our approach (i) can be used in young or
546 regenerating un-managed forests with a low "largest tree" diameter threshold and (ii) is
547 compatible with recent remote sensing approaches able to single out canopy trees and
548 describe their crown and height metrics (Ferraz *et al.*, 2016; Coomes *et al.*, 2017).

549 **Aboveground biomass model from the largest trees, a multiple opportunity**

550 Globally, the N_{LT} model for the 20 largest trees allows plot biomass to be predicted with 17.9%
551 error. This result is a pan-tropical validation of results obtained in Central Africa (Bastin *et al.*,
552 2015). It opens new perspectives towards cost-effective methods to monitor forest structures
553 and carbon stocks through largest trees metrics, i.e. metrics of objects directly intercepted by
554 remote-sensing products.

555 Developing countries willing to implement Reduction of Emissions from Deforestation and
556 Forest Degradation (REDD+) activities, shall also report on their carbon emissions and develop
557 a national reference level (IPCC, 2006; Maniatis & Mollicone, 2010). However, most tropical
558 countries lack capacities to assume multiple, exhaustive and costly forest carbon inventories
559 (Romijn *et al.*, 2012). By measuring only a few large trees per hectare, our results show that it
560 is possible to obtain unbiased estimates of aboveground C stocks in a time and cost-efficient
561 manner. Assuming that 400 to 600 trees $D > 10$ cm are measured in a typical 1-ha sample
562 plot, monitoring only 20 trees is a significant improvement. Although finding the 20 largest trees
563 in a plot of several hundred individuals requires evaluating more than 20 trees, in practice, a
564 conservative diameter threshold could be defined to ensure that the 20 largest trees are
565 sampled. An alternative approach could also be found in the development of relascope-based
566 approach adapted to detection of the largest trees in tropical forests. Using such approach
567 would facilitate rapid field sampling in extensive areas to produce large scale AGB estimates.
568 Those could fulfil the needs in calibration and validation of current and forthcoming space
569 missions focused on aboveground biomass.

570 Our findings also point towards the potential effectiveness of using remote sensing techniques
571 to characterize canopy trees for inferring entire forest stands attributes. Remote sensing data
572 could be used for direct measurement (e.g. tree level metrics such as height, crown width,
573 crown height) of the largest trees as a potential alternative to indirect development of complex
574 metrics (e.g. mean canopy height, texture) used to extrapolate forest properties. While the use
575 of single-tree approach has shown some limitations to extrapolate plot metrics (Coomes *et al.*,
576 2018), we have still to investigate their potential to identify largest trees. Some further
577 refinements are needed, but most of the tools required to develop “largest trees” models are
578 readily available. In particular, Ferraz *et al.* (2016) developed an automated procedure to locate
579 single trees based on airborne LiDAR data, to measure their height and crown area. Crown
580 area could further be linked to basal area, as the logarithm of crown area is consistently
581 correlated with a slope of 1.2-1.3 to the logarithm of tree diameter across the tropics (Blanchard
582 *et al.*, 2016). Regarding wood density, hyperspectral signature and high resolution topography

583 offers a promising way to assess functional traits remotely (e.g. Asner *et al.*, 2017; Jucker *et*
584 *al.*, 2018) which could potentially provide proxies of wood density. Alternative approaches
585 could focus on the development of plot-level AGB prediction by replacing the basal area of the
586 largest trees with their crown metrics. While the measurement of crown areas has yet to be
587 generalized when inventorying plots, several biomass allometric models already partition trunk
588 and crown mass (Ploton *et al.*, 2016; Coomes *et al.*, 2017; Jucker *et al.*, 2017).

589 The main limitation of our approach lies in the limited inference that can be made on the
590 understory and sub-canopy trees. We show that most of the remaining variance is explained
591 by variations in diameter structures, and in particular among the total stem density.
592 Interestingly, stem density was generally identified as a poor predictor of plot biomass in
593 tropical forests (Slik *et al.*, 2010; Lewis *et al.*, 2013). However, our results show that stem
594 density explains most of the remaining variance (Table S1). This suggests that, in addition to
595 trying to understand large-scale variations in large trees and other plot metrics, which can be
596 directly quantified from remote sensing, we should also put more effort into understanding
597 variation in smaller trees, which mainly drives total stem density and the total floristic diversity.
598 Smaller trees are also essential to characterize forest dynamics and understand changes in
599 carbon stocks. Several options are nonetheless possible from remote sensing, considering the
600 variation in lidar point density below the canopy layer (D'Oliveira *et al.*, 2012), the distribution
601 of leaf area density (Stark *et al.*, 2012, 2015; Tang & Dubayah, 2017; Vincent *et al.*, 2017) or
602 the use of multitemporal lidar data to get information on forest gap generation dynamics and
603 consequently on forest diameter structure (Kellner *et al.*, 2009; Farrior *et al.*, 2016).

604 **Large trees in degraded forests**

605 If large trees are a key feature of unmanaged forests, they are conspicuously absent from
606 managed or degraded forests. Indeed, large trees are targeted by selective or illegal logging,
607 and are the first to disappear or to suffer from incidental damages when tropical forests are
608 exploited for timber (Sist *et al.*, 2014). The loss of largest trees drastically changes forest
609 structures and diameter distributions, and their loss is likely to counteract the consistency in
610 forest structures observed through this study. Understanding how, or whether, managed

611 forests deviate from our model predictions could help characterize forest degradation, which
612 accounts for a large fraction of carbon loss worldwide (Baccini *et al.*, 2017), acknowledging
613 that rapid post-disturbance biomass recovery (Rutishauser *et al.*, 2015) will remain hard to
614 capture.

615 **Conclusion – towards improved estimates of tropical forest biomass**

616 The acquisition, accessibility and processing capabilities of very high spatial, spectral and
617 temporal resolution remote sensing data has increased exponentially in recent years (Bastin
618 *et al.*, 2017). However, to develop accurate global maps, we will have to obtain a greater
619 number of field plots and develop new ways to use remote sensing data. Our results provide
620 a step forward for both by (i) drastically decreasing the number of individual tree measurements
621 required to get an accurate, yet less precise, estimate of plot biomass and (ii) opening the way
622 to direct measurement of plot metrics measured from remote sensing to estimate plot biomass.
623 As highlighted by Clark and Kellner (2012), new biomass allometric models relating plot-level
624 biomass measured from destructive sampling and plot-level metric measured from remote-
625 sensing products should be developed, as an alternative to current tree-level allometric
626 models. Such an effort will largely lower operational costs and uncertainties surrounding
627 terrestrial C estimates, and consequently, will help developing countries in the development of
628 national forest inventories and aid the scientific community in better understanding the effect
629 of climate change on forest ecosystems.

642 Jean-Phillipe Puyravaud, Estação Científica Ferreira Penna (MPEG) and the Andrew Mellon
643 Foundation and National Science Foundation (DEB 0742830). The forest plots in Nova
644 Xavantina and Southern Amazonia, Brazil was funded by grants from Project PELD-
645 CNPq/FAPEMAT (403725/2012-7; 441244/2016-5; 164131/2013); CNPq-PPBio
646 (457602/2012-0); productivity grants (CNPq/PQ-2) to B. H. Marimon-Junior and B. S. Marimon;
647 Project USA-NAS/PEER (#PGA-2000005316) and Project ReFlor FAPEMAT 0589267/2016.
648 And finally, we thank Helen Muller-Landau for her careful revision and comments of the
649 manuscript.

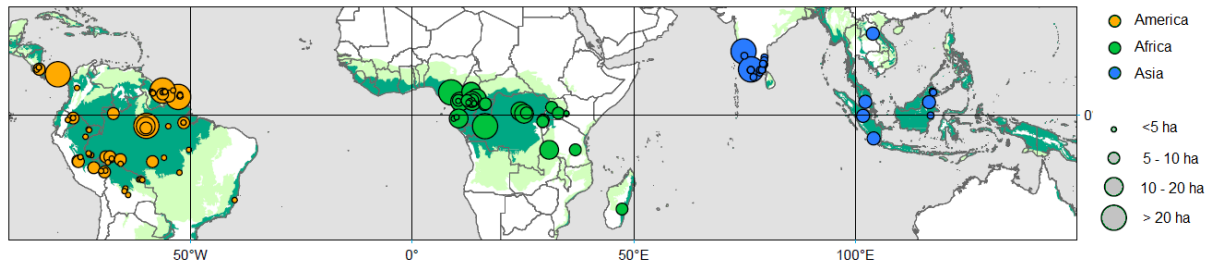

650 **Contributions**

651 J.F.Bastin and E.Rutishauser conceptualized the study, gathered the data, performed the
652 analysis and wrote the manuscript. All the co-authors contributed by sharing data and
653 reviewing the main text. A.R.Marshall, J.Poulsen and J.Kellner revised the English.

654 **Conflict of interest**

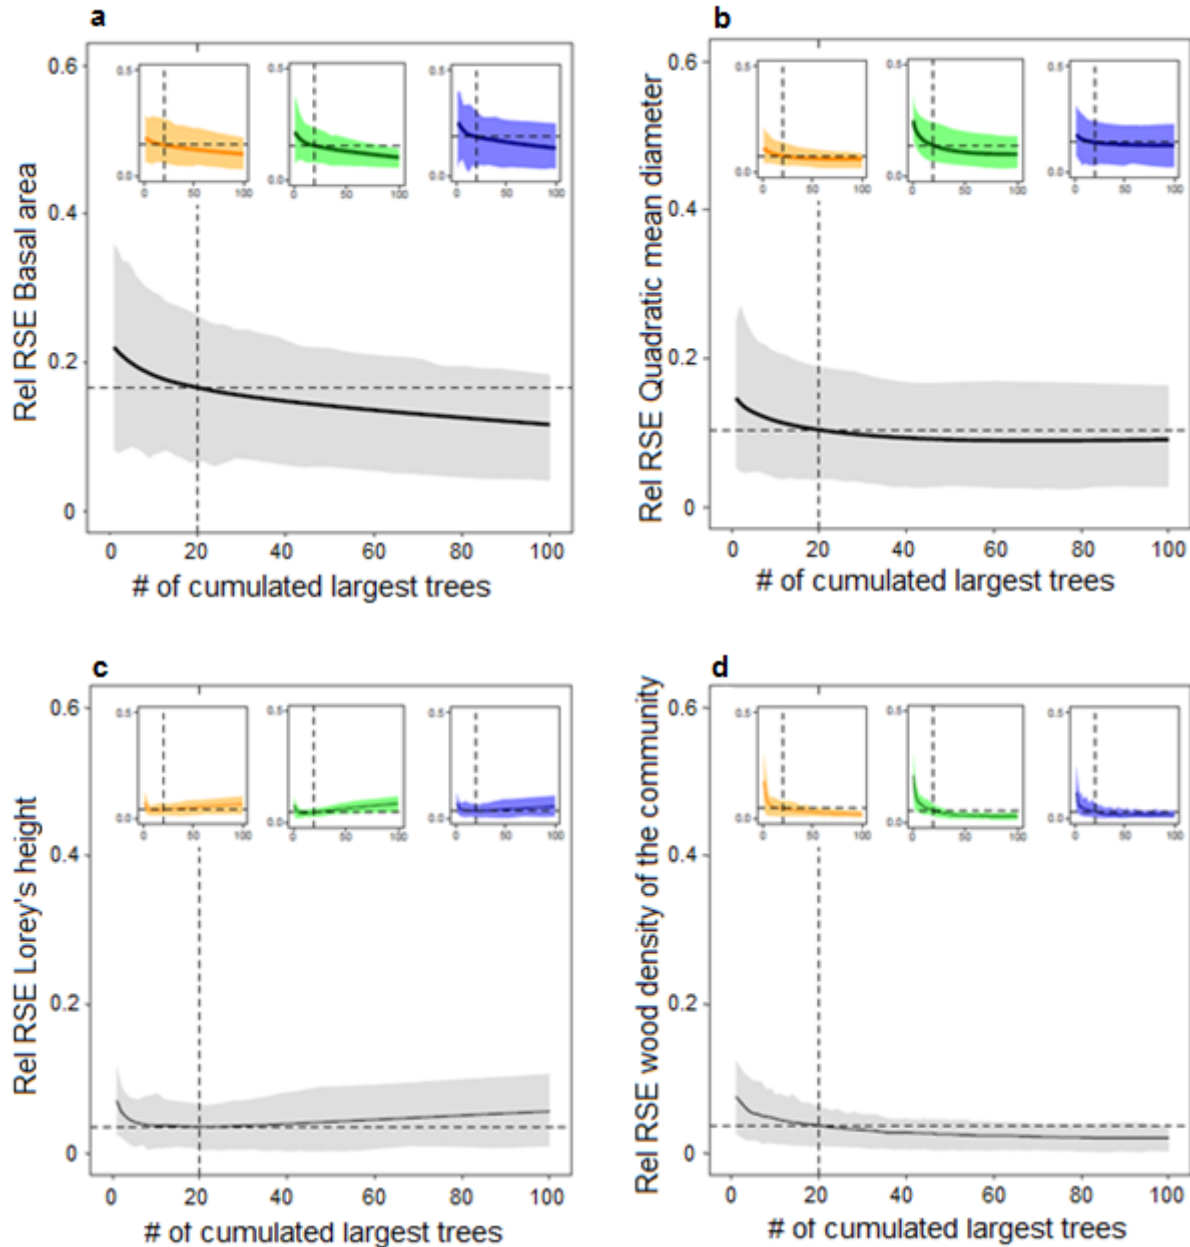

655 The authors declare there is no conflict of interest associated to this study.

656 **Figures**

657

658 **Figure 1. Geographic distribution of the plot database.** We used 867 plots of 1 hectare
659 from 118 sites. Dots are colored according to floristic affinities (Slik et al. 2015), with America,
660 Africa and Asia respectively in orange, green and blue. They are also sized according the total
661 area surveyed in each site. In the background, moist forests are displayed in dark green and
662 dry forest in light green.

663

664 **Figure 2. Quality of the prediction of plot metrics from largest trees.** Variation of the

665 relative Root Mean Square Error (rRMSE) of the prediction of plot metric from i largest trees

666 versus the cumulative number of largest trees for (a) basal area, (b) quadratic mean diameter,

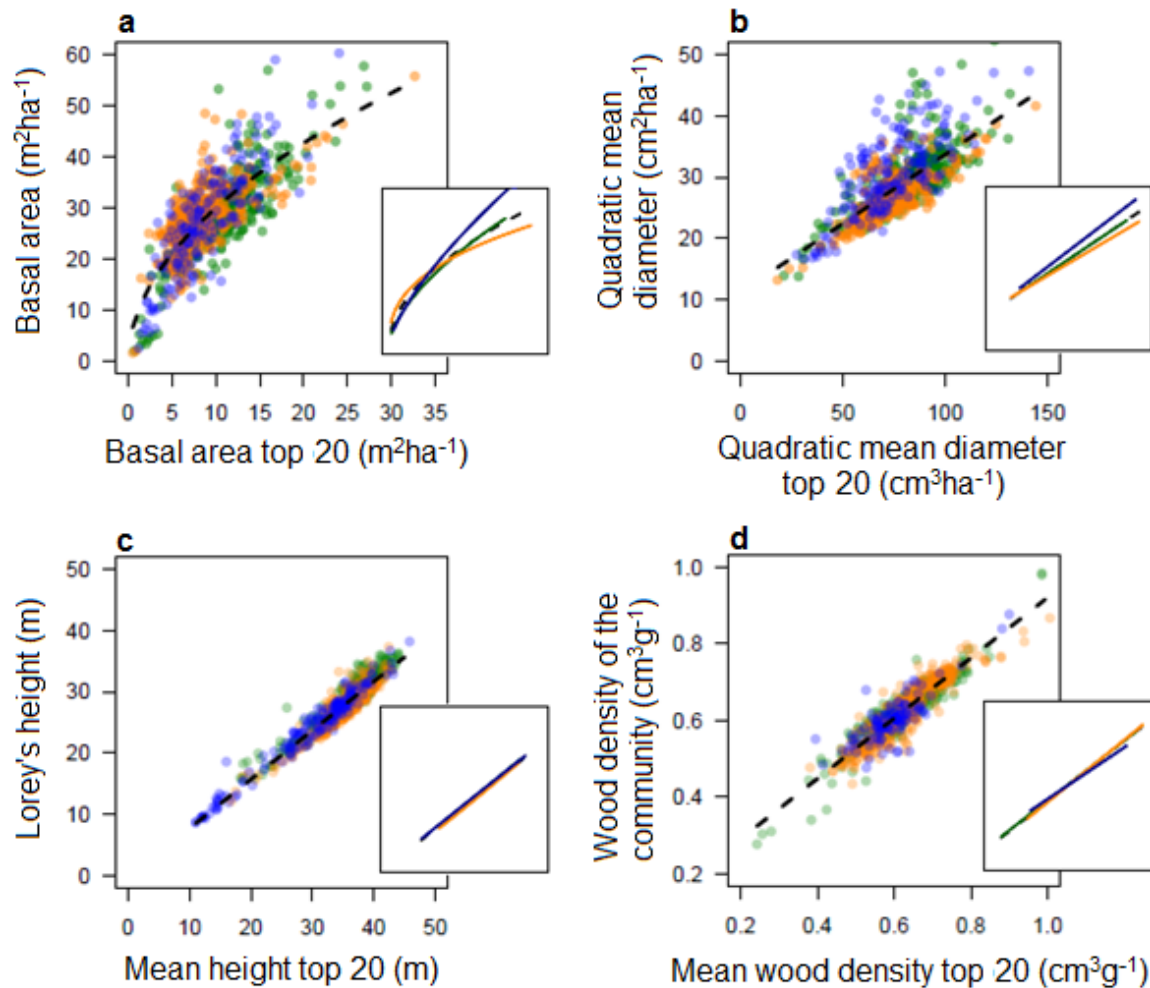

667 (c) Lorey's height and (d) wood density weighted by the basal area. Results are displayed at

668 the pan-tropical level (main plot in grey) and at the continental level (subplots; orange =

669 America; green = Africa; blue = Asia). The solid line and shading shows the mean rRMSE and

670 the 5th and the 95th percentiles. Dashed lines represent the mean rRMSE observed for each

671 model, when considering the 20 largest trees.

672

673 **Figure 3. Prediction of plot metrics (y-axis) from the 20 largest trees (x-axis).** Results are

674 shown for (a) basal area, (b) quadratic mean diameter, (c) Lorey's Height and (d) wood density

675 weighted by the basal area. Each dot corresponds to a single plot, colored in orange, green

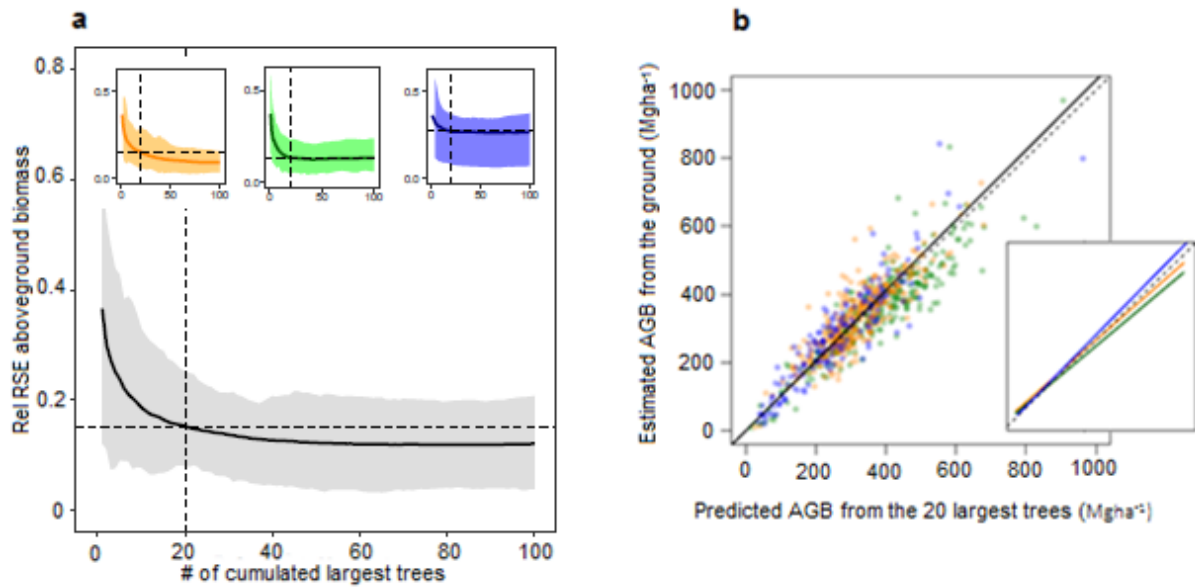

676 and blue for America, Africa and Asia respectively. Both pan-tropical (black dashed lines) and

677 continental (coloured lines) regression models are displayed. These results show that

678 substantial part of remaining variance, i.e. not explained by largest trees, is found when

679 predicting the basal area and the quadratic mean diameter, with slight but significant

680 differences between continents.

681

682 **Figure 4. Prediction of AGB from plot metrics of the 20 largest trees.** Results are shown
 683 for the 867 plots, among the three continents colored orange, green and blue for America,
 684 Africa and Asia respectively. The regression line of the model is shown as a continuous black
 685 line while the dashed black line shows a 1:1 relationship. The figure shows an unbiased
 686 prediction of AGB across the 867 plots, with slight but significant differences between the 3
 687 continents.

688

689 **Figure 5. Predicted vs. observed residuals of aboveground biomass predicted from the**

690 **20 largest trees.** Residuals are explored at three different levels: (a) plot, (b) site [without

691 considering the diameter structure as an explanatory variable], (c) site [considering the

692 diameter structure] and (d) along the stem density of medium size trees. America, Africa and

693 Asia are colored in orange, green and blue respectively. The figures show a good prediction

694 of residuals in (a) and (b), driven by stem density, and a less biased prediction in (c), driven by

695 the diameter structure. Variance of observed residuals are also well explained by the stem
696 density of medium size trees (d), which mainly drive the first axis of the PCA.

697

698 Figure 6. Comparison across continents of aboveground biomass prediction per site and their
 699 contribution to different share of the diameter structure. Africa, Asia and America, are colored
 700 in green, blue and orange, respectively. The distribution of the residuals of pan-tropical
 701 aboveground biomass prediction from the 20 largest trees (a) shows predictions are slightly
 702 overestimated in Africa (+3%), and slightly underestimated in Asia (-3%) and America (-5%).
 703 The proportion of aboveground biomass in the 20 largest trees (b) is highest in Africa (48%),
 704 followed by Asia (40%) and America (35%). The decomposition across four diameter classes
 705 (c-f, i.e. from 10 to 30, 30 to 50, 50 to 70 and beyond 70 cm) of their relative share of the total
 706 biomass shows that most of the biomass is found in the large trees in Africa, and in the small

707 to medium trees in America. Asia presenting a more balanced distribution of biomass across
708 the diameter structure.

709 **Tables**

710 **Table 1. Weight of each variable retained for the explanation of AGB residuals.** Weights
 711 are calculated as a type II sum of squares, which measures the decreased residual sum of
 712 squares due to an added variable once all the other variables have been introduced into the
 713 model. Results are shown for the exploration of residuals at the plot and at the site level, with
 714 and without consideration of the diameter structure. Weights are dominated by structural
 715 variables, and in particular the stem density and the diameter structure. Height, wood density
 716 and continent have also a non-negligible influence on residuals.

Level of residual	Parameter	Weight	717
Plot	Stem density*	79	
	Continent*	18	
	Lorey's height*	1	
	Major soil types	1	
	Temperature	1	
	Wood density weighted by the basal area	0	
	Rainfall	0	
Site without diametric structure	Stem density*	54	
	Continent*	28	
	Wood density weighted by the basal area*	11	
	Rainfall	3	
	Major soil types	3	
	Temperature	2	
	Lorey's height	0	
Site with diametric structure	PCA axis 1*	69	
	Lorey's height*	23	
	Rainfall*	3	
	Major soil types	3	
	Continent	1	
	Temperature	1	
	Wood density weighted by the basal area	0	
	PCA axis 2	0

1110 **Data accessibility**

1111 Data for plots in the CTFs network are available through the online portal at
1112 <http://www.forestgeo.si.edu>; in the Forestplot network at <https://www.forestplots.net/> and in
1113 the TEAM network at <http://www.teamnetwork.org/>.

1114 **Biosketches**

1115 Jean-Francois Bastin is a Post-Doctoral Fellow of the Crowther Lab at the Institute of
1116 Integrative Biology, Department of Environmental Systems Science, ETH-Zurich. He is an
1117 ecologist and a geographer using remote sensing to study the effect of global change on
1118 terrestrial ecosystems.

1119 Ervan Rutishauser is a Post-doctoral Fellow at Smithsonian Tropical Research Institute,
1120 broadly interested in understanding environmental resilience to natural or human-induced
1121 disturbances. He aims at providing rigorous and practical evidences to trigger a shift towards
1122 better resources management and conservation.

1133 **prediction of plot-metrics from the 20 largest trees.**

1134
 1135 **Supplementary figure 1. Cross-continent comparison of plot-metrics distribution**
 1136 **averaged at the site level.** Figures illustrates respectively the distribution of the values for the
 1137 quadratic mean diameter (a), basal area (b), Lorey's height (c), wood density (d) and
 1138 aboveground biomass (e).

Mean Height - 20 largest trees (m) - local HD

Mean Height - 20 largest trees (m) - Observed H

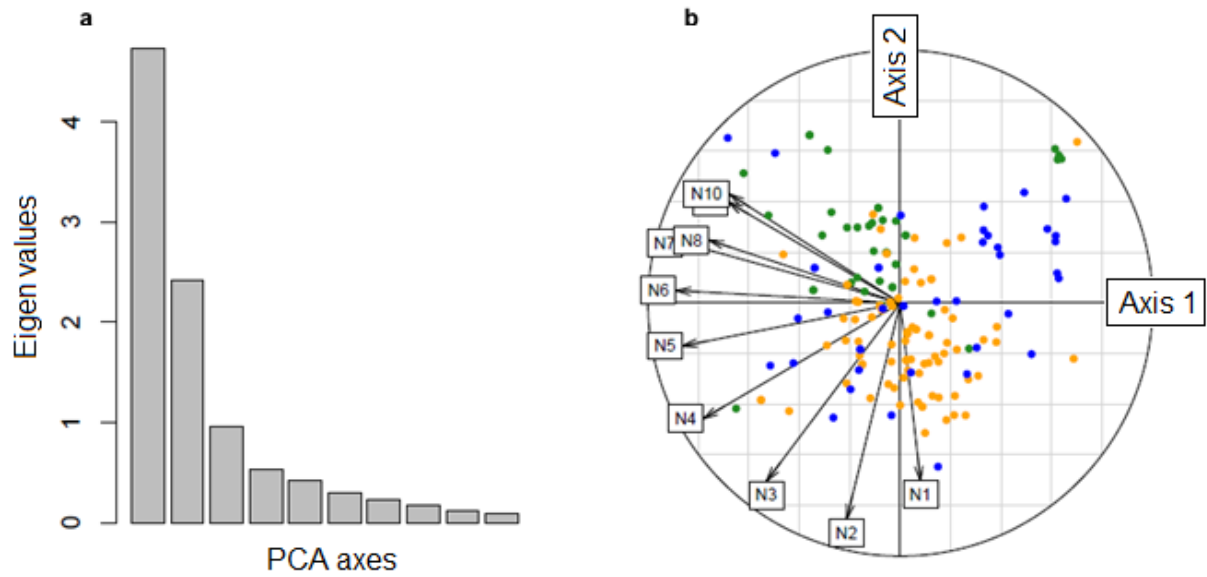

1139

1140 **Supplementary figure 2. Lorey's Height prediction from the 20 largest trees.** Figures

1141 show the results using (i) local D-H allometries for 20 sites (left subfigure) and (ii) using plots

1142 where height is measured on all trees in Malebo site in the Democratic Republic of the Congo

1143 (right subfigure).

1144

1145 **Supplementary figure 3. PCA on the diameter structure and corresponding mean**
 1146 **distribution for high contributions of axis 1 and axis 2.** (A) Illustration of top and low
 1147 percentile observed for each axis, with diameter distributions represented as the relative
 1148 difference with the average observed distribution.(B) Biplot with contribution to the PCA of all
 1149 the diameter classes, with the respective position of each site in the space defined by axis1
 1150 and 2. Axis 1 is driven by differences in global abundance of trees and axis 2 is driven by a
 1151 difference of balance between abundance of small vs. large trees. Colors represent continent,
 1152 with Africa, America and Asia respectively in green, orange and blue.

1153
1154

Supplementary figure 4. Cross-continent comparison of the relative residuals from the prediction of plot-metrics from the 20 largest trees. The relative residuals are generally low (<10%). Systematic small differences can however be found in America, where the quadratic mean diameter and Lorey's height tend to be slightly overestimated and the basal area slightly underestimated.
