Criteria for inclusion in the *Health Technology Assessment* journal

Reports are published in *Health Technology Assessment* (HTA) if (1) they have resulted from work for the HTA programme, and (2) they are of a sufficiently high scientific quality as assessed by the reviewers and editors.

Reviews in *Health Technology Assessment* are termed 'systematic' when the account of the search appraisal and synthesis methods (to minimise biases and random errors) would, in theory, permit the replication of the review by others.

HTA programme

Health Technology Assessment (HTA) research is undertaken where some evidence already exists to show that a technology can be effective and this needs to be compared to the current standard intervention to see which works best. Research can evaluate any intervention used in the treatment, prevention or diagnosis of disease, provided the study outcomes lead to findings that have the potential to be of direct benefit to NHS patients. Technologies in this context mean any method used to promote health; prevent and treat disease; and improve rehabilitation or long-term care. They are not confined to new drugs and include any intervention used in the treatment, prevention or diagnosis of disease.

The journal is indexed in NHS Evidence via its abstracts included in MEDLINE and its Technology Assessment Reports inform National Institute for Health and Care Excellence (NICE) guidance. HTA research is also an important source of evidence for National Screening Committee (NSC) policy decisions.

Background: Myeloma causes profound immunodeficiency and recurrent serious infections. There are approximately 5500 new UK cases of myeloma per annum, and one-quarter of patients will have a serious infection within 3 months of diagnosis. Newly diagnosed patients may benefit from antibiotic prophylaxis to prevent infection. However, the use of prophylaxis has not been established in myeloma and may be associated with health-care-associated infections (HCAIs), such as *Clostridium difficile*. There is a need to assess the benefits and cost-effectiveness of the use of antibacterial prophylaxis against any risks in a double-blind, placebo-controlled, randomised clinical trial.

Objectives: To assess the risks, benefits and cost-effectiveness of prophylactic levofloxacin in newly diagnosed symptomatic myeloma patients.

Design: Multicentre, randomised, double-blind, placebo-controlled trial. A central telephone randomisation service used a minimisation computer algorithm to allocate treatments in a 1 : 1 ratio.

Setting: A total of 93 NHS hospitals throughout England, Northern Ireland and Wales.

Participants: A total of 977 patients with newly diagnosed symptomatic myeloma.

Intervention: Patients were randomised to receive levofloxacin or placebo tablets for 12 weeks at the start of antimyeloma treatment. Treatment allocation was blinded and balanced by centre, estimated glomerular filtration rate and intention to give high-dose chemotherapy with autologous stem cell transplantation. Follow-up was at 4-week intervals up to 16 weeks, with a further follow-up at 1 year.

Main outcome measures: The primary outcome was to assess the number of febrile episodes (or deaths) in the first 12 weeks from randomisation. Secondary outcomes included number of deaths and infection-related deaths, days in hospital, carriage and invasive infections, response to antimyeloma treatment and its relation to infection, quality of life and overall survival within the first 12 weeks and beyond.

Results: In total, 977 patients were randomised (levofloxacin, $n = 489$; placebo, $n = 488$). A total of 134 (27%) events (febrile episodes, $n = 119$; deaths, $n = 15$) occurred in the placebo arm and 95 (19%) events (febrile episodes, $n = 91$; deaths, $n = 4$) occurred in the levofloxacin arm; the hazard ratio for time to first event (febrile episode or death) within the first 12 weeks was 0.66 (95% confidence interval 0.51 to 0.86; $p = 0.002$). Levofloxacin also reduced other infections (144 infections from 116 patients) compared with placebo (179 infections from 133 patients; p-trend of 0.06). There was no difference in new acquisitions of *C. difficile*, methicillin-resistant *Staphylococcus aureus* and extended-spectrum beta-lactamase Gram-negative organisms when assessed up to 16 weeks. Levofloxacin produced slightly higher quality-adjusted life-year gains over 16 weeks, but had associated higher costs for health resource use. With a median follow-up of 52 weeks, there was no significant difference in overall survival ($p = 0.94$).

Limitations: Short duration of prophylactic antibiotics and cost-effectiveness.

Conclusions: During the 12 weeks from new diagnosis, the addition of prophylactic levofloxacin to active myeloma treatment significantly reduced febrile episodes and deaths without increasing HCAIs or carriage. Future work should aim to establish the optimal duration of antibiotic prophylaxis and should involve the laboratory investigation of immunity, inflammation and disease activity on stored samples funded by the TEAMM (Tackling Early Morbidity and Mortality in Myeloma) National Institute for Health Research Efficacy and Mechanism Evaluation grant (reference number 14/24/04).

Trial registration: Current Controlled Trials ISRCTN51731976.

Plain English summary

What is the problem?

Myeloma is a type of cancer that develops from cells in the bone marrow, called plasma cells, which are part of the immune system. Because myeloma affects the immune system, people who have it are at greater risk of picking up infections. This risk is higher at the start of antimyeloma therapy when the myeloma is active.

What did the study do?

The trial looked to see if the risk of getting an infection can be reduced, rather than waiting to see if an infection developed and then treating it. An antibiotic already used all over the world, called levofloxacin was tested. Half of the patients ($n = 489$) took levofloxacin for 12 weeks and the other half ($n = 488$) were given a dummy tablet (placebo). The aim was to see if taking levofloxacin at the start of antimyeloma therapy reduced the risk of getting an infection. Alongside this, we evaluated three important groups of antibiotic-resistant bacteria to see whether or not the use of preventative levofloxacin increased the number of these resistant bacteria living in the body.

In addition, the overall survival, economic impacts and the impact of using preventative antibiotics on patients' quality of life and response to antimyeloma treatment were evaluated.

What did the study find?

During the 12 weeks from new diagnosis of myeloma, the addition of prophylactic levofloxacin to active myeloma treatment significantly reduced the number of febrile episodes and deaths [134 (febrile episodes alone, $n = 112$; febrile episodes plus death, $n = 7$; deaths alone, $n = 15$) out of 488 (27%) placebo patients vs. 95 (febrile episodes alone, $n = 87$; febrile episodes plus death, $n = 4$; deaths alone, $n = 4$) out of 489 (19%) levofloxacin patients; $p = 0.002$] without increasing antibiotic-resistant bacteria.

Scientific summary

Background

Myeloma is a cancer of bone marrow plasma cells that causes profound immunosuppression. There is a high early-death rate, with the biggest single cause being infection. Recent improvements in overall survival in myeloma mean that prevention of early death has become more pressing, especially as early death affects all prognosis groups.

Antibiotic prophylaxis is likely to be the single most effective measure to prevent early death in myeloma patients. Treatment with antibiotics once an infection is established is probably not sufficient, as the early-death rate in older patients has remained constant over a 20-year period, despite improvements in supportive care. The use of antibiotic prophylaxis is evidence-based established practice in some areas of medicine (e.g. neutropenia, human immunodeficiency virus) but the recent rise in health care-associated infections (HCAIs) has raised concern about the risks of antibiotic prophylaxis. Although the benefits are well established, there is concern that clinicians are withholding antibiotic prophylaxis because of fears of HCAI. Extrapolating from current data, the benefits of prophylaxis are likely to outweigh the risks of HCAI. However, there has not been a large trial looking at the benefits of antibiotic prophylaxis compared with the risks of HCAI. Examination of the organisms causing infection in myeloma suggests that levofloxacin, given for the first 12 weeks, is the best antibiotic for prophylaxis.

Reducing infection in the first 3 months from diagnosis may increase the myeloma response rate primarily by reducing the number of interruptions of antimyeloma treatment. There is also some evidence for a role for infections driving myeloma pathogenesis directly, although further proof is required to confirm this effect in vivo.

Objectives

To assess the risks, benefits and cost-effectiveness of levofloxacin in newly diagnosed symptomatic myeloma by means of a prospective, multicentre, randomised, double-blind, placebo-controlled trial.

End points

Primary outcome from start of trial treatment to 12 weeks

- Time to first febrile episode or death.
  A febrile episode is identified and counted by a single oral temperature of $\geq 38\,°C$ (recorded either by a health-care professional *or* by the patient/carer, provided that the patient/carer has been trained and assessed as being competent in temperature taking) *and* by that patient then being given anti-infectives.

Secondary outcomes from start of trial treatment to 12 weeks

- Number of deaths and infection-related deaths.
- Number of days in hospital.
- Number of days in hospital on anti-infectives.
- Carriage and invasive infections with *Staphylococcus aureus*, *Clostridium difficile* and extended-spectrum beta-lactamase (ESBL) coliforms.

- Patient characteristics, steroid use and indices of immunocompetence and their relation to colonisation by, and development of, infection with *S. aureus*, *C. difficile* and ESBL coliforms, non-HCAIs and Eastern Cooperative Oncology Group (ECOG) performance status.
- Number of clinically documented total infections, episodes of severe sepsis (Common Terminology Criteria for Adverse Events grade 3 or 4) and suspected infections (defined as any episode in which the patient was given anti-infective treatment for a suspected infection and any recorded temperature of < 38 °C).
- Incidence of microbiologically proven infections, the pathogens and their susceptibility to antibacterials.
- Number of days on anti-infective therapy for treatment of infection.
- Response to antimyeloma therapy and its relationship to infection.

Secondary outcomes from start of trial treatment to beyond 12 weeks

- Carriage and invasive infections with *S. aureus, C. difficile* and ESBL coliforms between 12 and 16 weeks to assess for delayed effects from the intervention, which is stopped at 12 weeks.
- Response to antimyeloma therapy at 16 weeks.
- Quality of life (QoL).
- Health economics.
- Overall survival.

Trial design and methodology

Multicentre, randomised, double-blind, placebo-controlled trial.

Patients were randomised to receive levofloxacin or placebo tablets for 12 weeks at the start of antimyeloma treatment. Treatment allocation was blinded and balanced by centre, estimated glomerular filtration rate (eGFR) and intention to give high-dose chemotherapy with autologous stem cell transplant. A central randomisation telephone service used a minimisation algorithm to generate a trial number and a drug pack number for each patient and allocate treatments in a 1 : 1 ratio. All investigators, patients and trial co-ordination staff were blinded to the treatment allocation. The levofloxacin and placebo tablets were packaged in coded, but otherwise identical, blister packs. Neither the patient nor the clinical team responsible for the patient's care could break the treatment code. The treatment code could be broken only by the Emergency Scientific and Medical Services team at Guy's and St Thomas' Hospital.

Treatment and investigations

In the experimental arm, patients were given 500 mg of levofloxacin orally, once daily, for 12 weeks (dose reduced in patients with renal impairment).

In the control arm, patients were given placebo orally, once daily, for 12 weeks (dose reduced in patients with renal impairment).

All patients received antimyeloma treatment and supportive care including bisphosphonates as per standard practice. If it was intended to give patients high-dose chemotherapy with autologous stem cell transplant, this information was collected at randomisation and taken into account during stratification. When patients were within 14 days either side of starting a programme of antimyeloma treatment, they received two levofloxacin (dose of 250 mg) or placebo tablets daily for 12 weeks. The start of the antimyeloma treatment was determined as the start of high-dose steroids or chemotherapy, whichever came first.

Estimated glomerular filtration rate provided locally, where possible, was assessed at baseline and reassessed at each scheduled trial visit to identify changes in renal function that would necessitate a change in dose of levofloxacin. It is recommended that eGFR was assessed within the 7- to 14-day period

prior to randomisation. Those patients with an eGFR of > 50 ml/minute/1.73 m^2 took two tablets once per day (dose of 500 mg), patients with an eGFR of 20–50 ml/minute/1.73 m^2 took one tablet daily (dose of 250 mg) and patients with an eGFR of < 20 ml/minute/1.73 m^2 took half a tablet daily (dose of 125 mg). Both the active and placebo tablets were identical in breakable form. Dose reductions were recorded on the front of the patient diary, which was provided at each trial visit in conjunction with a review of eGFR. At entry and at 4, 8, 12 and 16 weeks, central laboratory analysis of stool samples and nasal swabs for microbiology, blood and urine for paraprotein response and immune function were collected. QoL [is assessed via the EuroQoL-5 Dimensions (EQ-5D), European Organization for Research and Treatment of Cancer Quality of Life Questionnaire-C30 and the Hospital Anxiety and Depression Scale] and health economics data were collected via the patient diaries.

Sample size determination

The final number of patients recruited was 977 (randomised to levofloxacin, $n = 489$; randomised to placebo, $n = 488$). The primary outcome measure was time to first febrile episode or death from all causes, using a Kaplan–Meier survival curve and log-rank analysis. Assuming that the proportion of patients experiencing a febrile episode or death is 30% in the first 3 months and that prophylactic antibacterials would reduce that rate to 20%, then recruiting 800 patients into the trial (400 patients in each arm) would allow differences in excess of 10% to be detected with 90% power using a two-sided test at the 5% level of significance. Recruiting 1000 patients into the trial (500 in each arm) would allow differences in excess of 8% to be detected with a 90% power using a two-sided test at the 5% level of significance. Recruiting 1000 patients would also allow detection of a levofloxacin-induced threefold increase in the rate of *C. difficile*-positive stools from 5% to 15% from entry to the trial to 12 weeks, with a 95% power and a 5% level of significance (two-sided test).

Other analyses included the incidence of suspected infections by site, severity and therapy; response to antimyeloma therapy and its relationship to infection; patient characteristics and indices of immunocompetence (blood leucocyte subset enumeration and antibacterial antibody titres) as prognostic markers for colonisation and invasive infection by antibiotic-resistant organisms; health economics; and QoL (by daily diary card and 4-weekly EQ-5D up to 16 weeks). With 1000 patients, reliable estimates can be reported for these secondary outcomes.

Follow-up

Patients were followed up at 4-weekly intervals up to 16 weeks, with a further follow-up at 1 year. Long-term follow-up will be collected for patients until the end of the trial by flagging with the Office for National Statistics and requesting copies of death certificates.

Key inclusion criteria

Patients were eligible for this trial if:

- they were aged ≥ 21 years and able to give informed consent
- they had newly diagnosed symptomatic myeloma based on internationally agreed criteria
- there was an intention to treat their myeloma actively
- they were within 14 days of starting, and no more than 14 days into, a programme of antimyeloma treatment
- they were able to provide written informed consent.

Key exclusion criteria

Patients were ineligible for this trial if they:

- had a contraindication to levofloxacin
- were women of childbearing age who were not willing to use appropriate methods of contraception to prevent pregnancy or women who were breastfeeding
- were thought to have a mandatory requirement for antibacterial prophylaxis.

- had received previous treatment for myeloma, except for the following –

  - local radiotherapy to relieve bone pain or spinal cord compression
  - prior bisphosphonate treatment
  - previous (< 5 years since diagnosis) or concurrent active malignancies except surgically removed basal or squamous cell carcinoma of the skin, treated carcinoma in situ of the breast or cervix, or incidental histological finding of prostate cancer (tumour, node, metastasis stage of T1a or T1b) [patients with remote histories (> 5 years) of other cured malignancies could be entered].

Results

Tackling Early Morbidity and Mortality in Myeloma (TEAMM) recruited 977 patients between August 2012 and April 2016 from 93 centres in the UK. The median age of participants was 67 years, 63% were male, 76% had an eGFR of > 50 ml/minute/1.73 m^2, 54% had planned high-dose chemotherapy with autologous stem cell transplantation, 76% had ECOG performance status 0 or 1 and 71% presented with bone disease. In total, 977 patients were randomised (levofloxacin, $n = 489$; placebo, $n = 488$); 24 patients withdrew before their first assessment and were censored at their date of withdrawal for the primary outcome.

A total of 134 (27%) events (febrile episode alone, $n = 112$; febrile episodes plus death, $n = 7$; deaths alone, $n = 15$) occurred in the placebo arm and 95 (19%) events (febrile episode alone, $n = 87$; febrile episodes plus death, $n = 4$; deaths alone, $n = 4$) occurred in the levofloxacin arm. The hazard ratio (HR) for time to first event (febrile episode or death) within the first 12 weeks was 0.66 [95% confidence interval (CI) 0.51 to 0.86; $p = 0.002$]. Cox regression models adjusting for slight imbalances between baseline factors did not identify any significant independent prognostic factors in the presence of treatment (adjusted HR 0.73, 95% CI 0.53 to 0.99; $p = 0.04$) in favour of levofloxacin.

Levofloxacin also reduced other infections (144 infections from 116 patients) compared with placebo (179 infections from 133 patients) (p-trend of 0.06). There was no difference in new acquisitions of *C. difficile*, methicillin-resistant *S. aureus* and ESBL Gram-negative organisms when assessed up to 16 weeks. Levofloxacin produced slightly higher quality-adjusted life-year gains over 16 weeks compared to placebo but had associated higher costs for health resource use. With a median follow-up of 52 weeks, there was no significant difference in overall survival ($p = 0.94$).

Conclusions

During the 12 weeks from new diagnosis, the addition of prophylactic levofloxacin to active myeloma treatment significantly reduced febrile episodes and deaths without increasing HCAIs or carriage.

Trial registration

This trial is registered as ISRCTN51731976.

Funding

Chapter 1 Introduction

Background

Myeloma is a cancer of bone marrow plasma cells that causes anaemia, skeletal fractures, renal failure and profound immunodeficiency. There are approximately 5500 new cases of myeloma in the UK per annum.[1] However, the overall prevalence is increasing, given the improved survival rates over the past four decades.[2] The median age at presentation is approximately 70 years and only 15% of patients are aged < 60 years. Myeloma has a higher incidence in African-Caribbean ethnic groups than in Caucasians, but there are few other distinctive epidemiological features.[3] The majority of cases present de novo, but it is now recognised that this is preceded by an asymptomatic monoclonal gammopathy of undetermined significance phase in virtually all patients.[4]

Myeloma causes profound immunodeficiency and recurrent serious infections. One-quarter of patients will have a serious infection within 3 months of diagnosis. Ten per cent of patients die within the first 60 days of diagnosis, with bacterial infection directly causing 45% of these deaths.[5] Recent advances in antimyeloma treatment have improved overall survival significantly, yet this high early-death rate remains little changed, affecting all prognostic groups. Patients who may have survived long term with current antimyeloma treatment are dying soon after diagnosis, with the biggest single cause being bacterial infection. Therefore, newly diagnosed myeloma patients may benefit from antibacterial prophylaxis to prevent infection, hospital admission and early death. Reducing infection may also improve response to antimyeloma treatment by reducing interruptions of antimyeloma treatment and reducing immune responses to infection that promote myeloma cell survival and growth. In patients with other causes of immunodeficiency, such as neutropenia, asplenia, human immunodeficiency virus infection or reflux nephropathy, the importance of prophylactic antibiotics to prevent infection is well established and the administration of prophyactic antibiotics is common practice in the NHS. However, their usefulness in myeloma has not been established. Furthermore, some of the studies that established the use of antibacterial prophylaxis in other conditions predate the current rise in health care-associated infections (HCAIs), such as *Clostridium difficile*. The data from these older trials may not reflect current risks associated with antibiotic prophylaxis and so there is a need to reassess the effect of antibiotic prophylaxis on HCAI.

Existing research

Large studies in Europe and North America have identified a high mortality rate (8–20%) in the first 3 months following a diagnosis of myeloma, with bacterial infection being the single biggest identifiable cause.[5–8] Analysis of 3107 myeloma patients registered into UK Medical Research Council (MRC) trials from 1980 to 2002 showed that 10% of patients died within 60 days of trial entry and that 45% of these deaths were directly attributable to bacterial infection.[5]

In the 'MRC myeloma 9' trial,[9] which recruited between 2003 and 2008, overall incidence of infection in non-intensively treated patients was 214 out of 692 (30.9%), with a median time to infection from first diagnosis of myeloma of 43 days. Recent advances in antimyeloma treatment have improved survival significantly, yet this high early-death rate has remained unchanged for > 30 years and affects all prognostic groups. This suggests that current supportive care strategies, including the treatment of an infection once established, may be insufficient. *Streptococcus pneumoniae*, *Staphylococcus aureus* and *Escherichia coli* are the most frequent types of bacterial infection in myeloma patients.[10–15] The risk of these infections is associated with myeloma disease activity and abates as the disease is brought under control with antimyeloma treatment.

The mechanism by which the risk of infection is increased in the presence of active myeloma disease is not well understood. Over 90% of 3218 MRC myeloma trial patients had reduced levels of normal antibodies,[16] and these patients' susceptibility to bacterial chest infections is characteristic of antibody deficiency. However, a previous MRC trial (MacLennan ICM, Chapman C, Hazelwood M, North J. University of Birmingham, 1993) of immunoglobulin G (IgG) replacement treatment (double-blind, randomised, placebo-controlled trial of 203 patients) did not significantly reduce mortality or morbidity from infection in the first 3 months after diagnosis, despite effectively increasing total serum IgG levels and titres against specific bacterial pathogens. Myeloma patients are not usually neutropenic at presentation, and, in one study, only 11 out of 135 myeloma patients dying of infection within 60 days of diagnosis had a neutrophil count of $< 2.0 \times 10^9$/l.[5] Other factors associated with active myeloma disease that might increase the risk of infection include low serum complement component 4 (C4) levels, increased transforming growth factor beta and increased interleukin 10.[17]

Antibacterial prophylaxis is an obvious strategy to prevent infection, hospital admission and early death in these patients. Of the only two trials[18,19] of prophylactic antibiotics in early myeloma, one prospective randomised study[18] was with co-trimoxazole in the early 1990s. This showed a reduction in bacterial infections with prophylactic co-trimoxazole (2/28 treated vs. 11/26 control patients) but the sample size was too small to detect reduced mortality. A recent trial[19] of 212 patients given ciprofloxacin, co-trimoxazole and placebo found no difference in the rate of infection. This study[19] was, again, underpowered to show differences in infection and mortality. The low incidence of all infections (22%) in this study raises the question whether or not the patients were representative of the normal myeloma clinic population. A retrospective analysis[20] of infections in 202 patients on new therapies found that 40% of patients had an infection within 6 months, with 80% of severe infections (16% of patients) occurring in the first cycle of treatment. Antibiotic prophylaxis was effective in preventing infections in those patients with surrogate markers of high tumour burden (monoclonal band of > 3 g/dl, platelet count of $< 130 \times 10^9$/l), but not in those without these parameters.

Antibiotic prophylaxis should be active against the bacteria commonly causing infections in the patients treated, should be given as ideally oral, once-daily medication to maximise adherence and efficacy, and should have few side effects. For all of the above reasons, the quinolones, particularly ciprofloxacin and levofloxacin, are now the most commonly used antibiotics for chemoprophylaxis.

Although less than one-tenth of myeloma patients dying of infection are neutropenic, the immunosuppressed state in both neutropenic and early myeloma patients leads to bacterial infection.[5] The common organisms causing infection in myeloma are *E. coli, S. pneumoniae, Klebsiella* spp., *S. aureus, Pseudomonas* spp., *Haemophilus* spp. and *Proteus* spp. These are similar to those organisms seen in neutropenic infections, although Gram-negative infections are more common in neutropenia. Thus, studies on the use of prophylactic antibiotics active against the common pathogens that cause infection in neutropenia are pertinent to myeloma patients.

A large meta-analysis[21] including 162 studies with 12,599 neutropenic patients found that all antibiotic prophylaxis significantly reduced the risk of death compared with placebo or no treatment [relative risk (RR) 0.66, 95% confidence interval (CI) 0.55 to 0.79]. Fluoroquinolone prophylaxis was the most effective and reduced the risk of all-cause mortality (RR 0.52, 95% CI 0.37 to 0.74), as well as of infection-related mortality, fever, clinically documented infection and microbiologically documented infections. Fluoroquinolone prophylaxis increased the risk of adverse events (AEs) (RR 1.52, 95% CI 0.79 to 2.92), but these were minor events. The benefit of reduction in infection-related mortality (RR 0.49, 95% CI 0.31 to 0.77) far outweighed any mortality from adverse effects because all-cause mortality was still markedly reduced (RR 0.52, 95% CI 0.37 to 0.74). These studies translate into a number needed to treat of 50 (95% CI 34 to 268) in order to prevent one death from all causes in neutropenic patients.

To date, only two studies[22,23] have reported differences in costs, and both showed a cost benefit for prophylaxis. These studies focused on individual resource use elements, such as the total cost of antibiotics or hospital inpatient days. None of the trials included a comprehensive cost analysis or a full economic evaluation.

Levofloxacin prophylaxis may, in addition to preventing infection, improve response to antimyeloma treatment. Delivery of antimyeloma treatment is often delayed by infection and so reducing infectious episodes may increase the amount of antimyeloma treatment given. There is epidemiological and laboratory evidence that the cytokines and inflammatory mediators associated with bacterial infection may promote the growth of myeloma cells.[17] By reducing infections, antibiotic prophylaxis may reduce myeloma growth and potentiate response to antimyeloma treatment. This will be the first trial to assess these factors.

However, quinolones, along with other antibiotics, are implicated in increased risk of colonisation with antibiotic-resistant bacteria and invasive infection by those bacteria. These HCAIs have been an ever-increasing problem to the NHS over the past 10 years, accounting for significant morbidity and mortality. Up to one in four people carry *S. aureus*, and *C. difficile* may be carried by 1–3% of healthy people.[24] Up to 30% of long-term hospitalised patients may carry *C. difficile*. There were 36,095 cases of *C. difficile*-associated diarrhoea in the UK in 2008–9.[24]

There is an increasing perception that antibiotic prophylaxis will increase numbers of HCAIs. A Midlands survey (carried out by the TEAMM trial management group) found that 24 haematologists did not use antibiotic prophylaxis alongside conventional myeloma chemotherapy, whereas eight haematologists did so in selected patients (unpublished audit). Half of the haematologists routinely used antibiotic prophylaxis in patients receiving intensive myeloma chemotherapy. Guidelines for the diagnosis and management of multiple myeloma published in 2009 by the UK Myeloma Forum[3] on behalf of the British Committee for Standards in Haematology state that:

> . . . *there is insufficient evidence to recommend the routine use of prophylactic antibiotics (Grade C recommendation; level IV evidence).*
>
> <div align="right">*Bird* et al.[3]</div>

There are insufficient data on the relationship between changes in carriage rate of potentially pathogenic organisms during antibiotic treatment and the risk of subsequent infection with the same organism. From meta-analysis[25] on antibiotic prophylaxis trials in neutropenia, there was no significant increase in *C. difficile* infection (7/1250 patients receiving a fluoroquinolone prophylaxis vs. 5/1279 receiving placebo or no treatment). Furthermore, recruitment to these trials predates Tackling Early Morbidity and Mortality in Myeloma (TEAMM) and the current problems with HCAIs by > 7 years. Although recent European guidelines[26] recommend fluoroquinolone prophylaxis in severe neutropenia, adherence to this recommendation is not universal. In trials in which resistance data have been reported, patients on fluoroquinolones did not develop more infections with pathogens resistant to the drug than patients on placebo (RR 1.04, 95% CI 0.73 to 1.5). By reducing the number of clinical infections, levofloxacin may reduce the total amount of antibiotics used in these patients and lessen the emergence of resistance.[22] Although the emergence of bacteria resistant to fluoroquinolones can occur in units using fluoroquinolone antibiotic prophylaxis, there are no clear data on whether or not patients are harmed as a result.[27,28]

In summary, the above data show that fluoroquinolone prophylaxis in neutropenia is very effective, but there are concerns about inducing fluoroquinolone-resistant organisms and HCAIs. This supports the equipoise position for this trial. No substantial trial of antibiotic prophylaxis in myeloma has been undertaken. The proven efficacy of levofloxacin in neutropenic patients and the sensitivity to levofloxacin of bacteria that cause infection in myeloma indicate that levofloxacin prophylaxis will also be effective in myeloma. The higher absolute risk of early death in myeloma (≈10% in the first 12 weeks from diagnosis in some risk groups) suggests that antibiotic prophylaxis may be even more effective in myeloma than in neutropenia. As there is a need for such an antibiotic trial in myeloma, it provides an excellent opportunity to collect data on HCAIs and quantify absolute risk of colonisation and infection during antibiotic prophylaxis. Data from the proposed trial will help to inform rational decisions about risks and benefits of antibiotic prophylaxis in many areas of medicine.

Research objectives

To assess the risks, benefits and cost-effectiveness of levofloxacin in newly diagnosed symptomatic myeloma by a prospective, multicentre, randomised, double-blind, placebo-controlled trial.

Research hypotheses

Levofloxacin used once daily as antibacterial prophylaxis in newly diagnosed symptomatic myeloma will:

1. reduce the rate of febrile episodes, hospitalisation and death
2. increase response to antimyeloma treatment
3. improve quality of life (QoL) and overall survival.

The trial will also test if levofloxacin affects the carriage of, and invasive infection by, three important groups of bacteria: (1) *C. difficile*, (2) *S. aureus* [including meticillin-resistant *Staphylococcus aureus* (MRSA)] and (3) extended-spectrum beta-lactamase (ESBL) coliforms, and will answer the following research questions:

1. Is the carriage of these organisms increased in patients receiving levofloxacin compared with those receiving placebo?
2. Is the carriage of these organisms associated with later invasive infections?
3. Does levofloxacin increase the rate of invasive infections by these three groups of organisms?

Chapter 2 Methods

Trial design

Tackling Early Morbidity and Mortality in Myeloma was a randomised, double-blind, placebo-controlled, multicentre phase III trial assessing the benefit of antibiotic prophylaxis and its effect on HCAIs in patients with symptomatic multiple myeloma. Target recruitment was originally 800 patients; however, this was extended to up to 1000 patients because of a high rate of recruitment and availability of investigational medicinal product (IMP). Patients were randomised in a 1 : 1 ratio to 500 mg of levofloxacin for 12 weeks or placebo to match. The primary outcome was time to first febrile episode or death. Secondary outcomes included, but were not limited to, response to antimyeloma treatment, carriage and invasive infections with *C. difficile*, MRSA and ESBL coliforms, QoL and overall survival.

Amendments to the protocol

Listed below are the amendments to the TEAMM protocol that were significant in increasing recruitment potential:

- The original protocol stated that patients had to begin trial treatment within 7 days of commencing antimyeloma treatment unless they were already on a broad-spectrum antibiotic for treatment of an infection. Before commencing recruitment, the number of days was increased from 7 to 14 days, irrespective of antibiotic treatment status. This allowed patients more time to consider the trial and research staff more time to obtain baseline samples without affecting the scientific integrity of the trial.
- Earlier versions of the protocol requested that a diagnostic skeletal survey be performed before patients could enter the trial. The protocol was amended prior to recruitment to relax the wording around diagnostic skeletal surveys. As skeletal surveys are part of the national diagnostic standard for multiple myeloma, it was felt that this did not need to be mandated and this was removed as a potential barrier to inclusion if patients had experienced a slightly different diagnostic journey.
- The protocol was changed to make it clear that patients were able to enter the trial even if they were taking another antibiotic treatment at the time of recruitment. Our lead microbiologist felt that it was probable that a number of patients would present for randomisation suffering from infections for which they were receiving antibiotic treatment. As long as there was no contraindication, patients could begin their trial treatment at the same time as their antibiotic treatment as this is in line with what is suggested when patients experience infections during the trial. It was felt that this would maximise the pool of eligible patients as long as details of this treatment were collected at baseline.
- In October 2015, the protocol was amended to allow the trial to recruit up to a further 200 patients as recruitment had been so successful and there was a surplus of IMP.
- Minor clarifications to eligibility criteria and clarifications on central laboratory testing were submitted alongside the above amendments.
- The primary end point was 'number of febrile episodes' analysed by a Kaplan–Meier curve and log-rank test (i.e. time-to-event analysis censoring deaths as an event). The primary end point, 'number of febrile episodes', was changed to 'time to febrile episode' to make this clear.

These amendments were all approved by the ethics committee.

Ethics and research and development approvals

Favourable opinion was given by National Research Ethics Service Committee West Midlands – Coventry and Warwickshire on 29 July 2011 (Research Ethics Committee reference number 11/WM/0220). Research and development (R&D) approval was obtained from University Hospitals Birmingham NHS Foundation Trust on 4 October 2011. Permissions to conduct the trial at each site were obtained from individual NHS trusts. Participating hospitals are listed in the *Acknowledgements*. All sites were activated between April 2012 and August 2015.

Sponsorship

TEAMM was co-ordinated by the Warwick Clinical Trials Unit (WCTU) at the University of Warwick. The University of Warwick had a co-sponsorship agreement with the University of Birmingham (acting as lead sponsor). The University of Birmingham was responsible for the provision of the chief investigator, serious adverse event (SAE) review, drafting and issuing clinical study site agreements, acting as custodian for trial samples collected, contracting with third parties and the haematology laboratory analysis. The University of Warwick was responsible for the administration of the trial, ensuring compliance with Good Clinical Practice, the design and approval of trial documents, and pharmacovigilance.

Participants

The trial sought to recruit patients with symptomatic myeloma who had not previously received active antimyeloma treatment for their disease. These patients were recruited from haematology departments in NHS hospital trusts covering England, Northern Ireland and Wales.

Inclusion criteria

Patients were eligible for this trial if:

- they were aged $\geq$ 21 years and able to give informed consent
- they had newly diagnosed symptomatic myeloma based on internationally agreed criteria
- there was an intention to treat (ITT) their myeloma actively
- they were within 14 days of starting, and no more than 14 days into, a programme of antimyeloma treatment
- they were able to provide written informed consent.

Exclusion criteria

Patients were ineligible for this trial if:

- they had a contraindication to levofloxacin
- they were known to have sensitivity/allergy to levofloxacin or other quinolones
- they had a history of tendon disorders related to fluoroquinolone administration
- they were receiving amiodarone or arsenic trioxide
- they were on active antiepileptic treatment
- they were women of childbearing age who were not willing to use appropriate methods of contraception to prevent pregnancy or women who were breastfeeding
- they were thought to have mandatory requirement for antibacterial prophylaxis (with the exception of *Pneumocystis* prophylaxis, if regarded as essential)
- they had received previous treatment for myeloma, except for the following:

  - local radiotherapy to relieve bone pain or spinal cord compression
  - prior bisphosphonate treatment
  - previous (< 5 years since diagnosis) or concurrent active malignancies, except surgically removed basal or squamous cell carcinoma of the skin, treated carcinoma in situ of the breast or cervix or incidental histological finding of prostate cancer [tumour, node, metastasis (TNM) stage of T1a or T1b]. Patients with remote histories (> 5 years) of other cured malignancies could be entered.

Settings and locations

A total of 93 NHS hospitals throughout England, Northern Ireland and Wales took part in the trial. All centres were required to provide confirmation of trust R&D approval to conduct the trial at each site. Each site's principal investigator (PI) and their delegated team underwent training on the trial protocol by the trial co-ordinator prior to the start of recruitment. This occurred via either a face-to-face meeting or a teleconference. Only when this training had been undertaken and all approvals and documentation were in place was the site opened to recruitment. Activation of recruitment was confirmed in writing by the trial co-ordinator.

Recruitment procedure

Participants were identified in new patient haematology clinics and multidisciplinary team meetings. The trial was then discussed with potential patients and the trial research nurse. Patients had to have had a new diagnosis of symptomatic myeloma and be within 14 days of their antimyeloma treatment start date. Once the trial had been discussed in detail and written patient information was provided, informed consent was taken following the process below.

Informed consent

There was no pre-agreed specified time to consent; however, it was recommended that patients were given at least 24 hours to go away, consider and talk to family about taking part in the trial. Consent was required to be informed and voluntary, with time for questions and reflection. However, the patient had the right also to make an immediate decision to consent.

Consent to participate was sought by the clinician involved in the patient's care, with the involvement of the research nurse in the consent discussion. Consent to participate was confirmed by the patient initialling each of the appropriate boxes on the consent form and signing the form in the presence of the person taking consent. A copy was given to the patient; one copy was also kept in the patient notes, and the original was kept in the local site file.

The TEAMM intervention

Patient randomisation and blinding

Written informed consent was obtained for all patients recruited to the trial. Randomisation of participants occurred through the WCTU Randomisation Service. Treatment allocation was performed using a minimisation algorithm and was stratified by hospital, estimated glomerular filtration rate (eGFR) and intention to give high-dose chemotherapy with autologous stem cell transplant (*Figure 1*).

At the point of randomisation, eligibility of the patient was confirmed and a check was performed on the consenting doctor to make sure they had been appropriately trained and delegated by the centre's PI. Confirmation of the patient's participation in the trial was sent to their general practitioner (GP) by the research team at the site using an approved template letter provided by the trial team. Trial treatment allocation was blinded to the clinicians, patients and the co-ordinating centre. The trial statistician allocated the term 'active' or 'placebo' in a 50 : 50 split to a list of 1500 randomly generated drug pack numbers. This list was sent (with password protection) to the drug packaging company that put the active drugs or placebo in the correctly labelled packs. This list was then used to build the bespoke randomisation and drug inventory system after the terms 'active' and 'placebo' were changed to 'A' or 'B' for concealment purposes. The trial statistician retained the master list, which revealed the identity of 'A' and 'B'. Ordering of the drug for each site was done via the database that picked at random an even number of 'A' pack numbers and 'B' pack numbers from those at the storage facility. Once these pack numbers were received by the sites, they were activated and available to be allocated to patients when randomised.

Emergency unblinding could be requested on grounds of safety by any clinician who was involved in the medical care of the patient. Emergency unblinding was performed by telephone contact with the Emergency Scientific and Medical Services team at Guy's and St Thomas' Hospital, which held a master unblinding list with the allocated pack numbers. Emergency unblinding was available 24 hours a day, 365 days a year, and was considered an option only when the patient's future treatment required knowledge of the trial treatment assignment.

Treatment

All patients entering TEAMM received antimyeloma treatment and supportive care including bisphosphonates as per standard practice at their hospital trust. If it was intended that the patient would proceed to high-dose chemotherapy with autologous stem cell transplant, this information was collected at randomisation and taken into account during stratification.
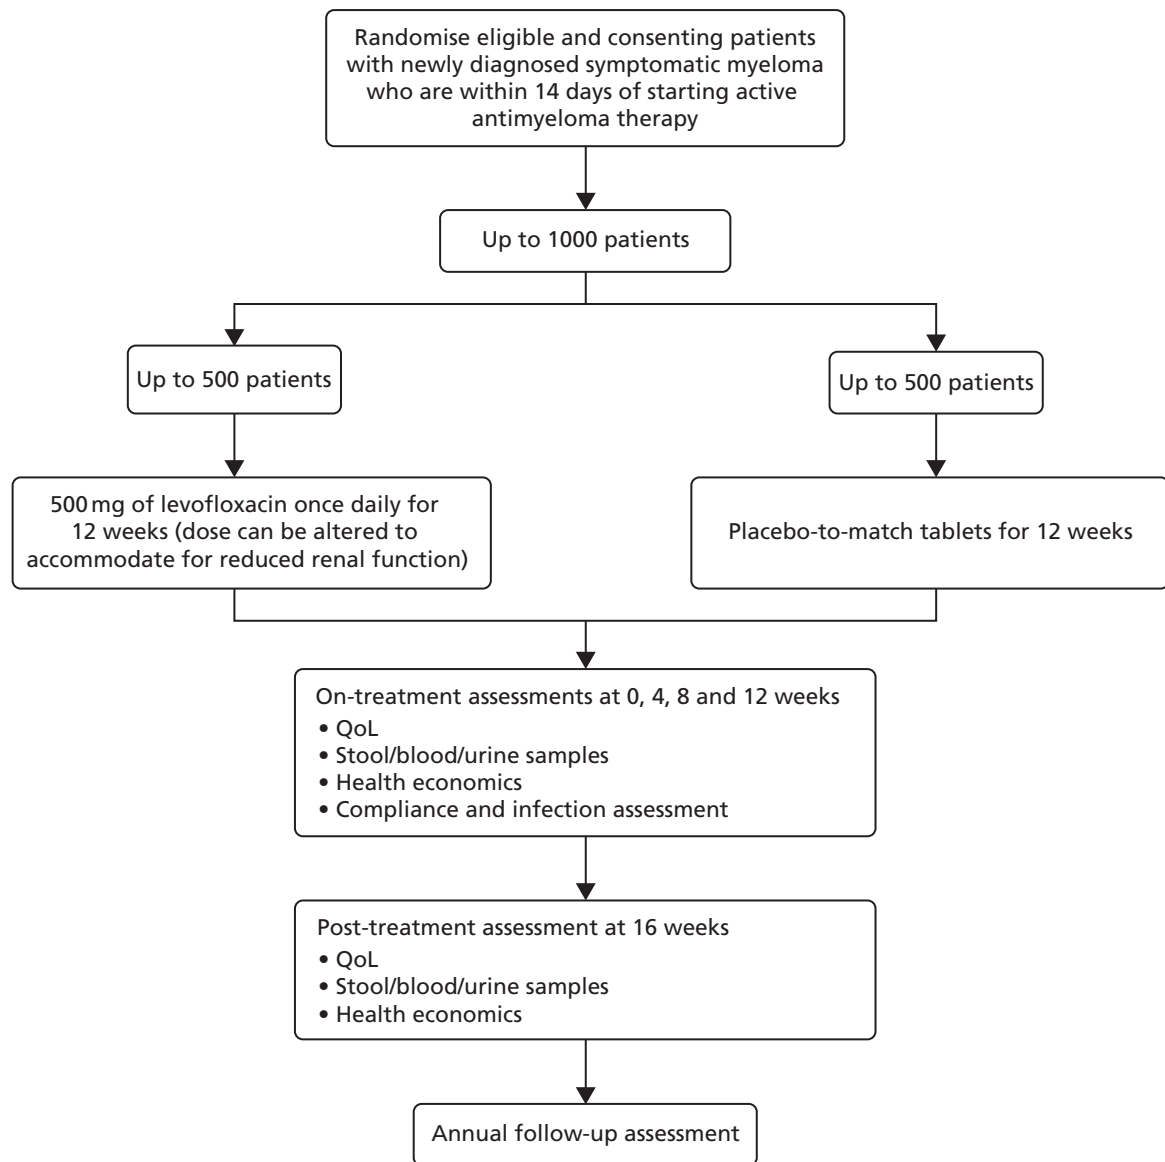

FIGURE 1 Trial schema.

When patients were within 14 days either side of starting a programme of antimyeloma treatment, they received 500 mg of levofloxacin or placebo-to-match tablets daily for 12 weeks (84 days). The start of the antimyeloma treatment was determined as the start of steroids or chemotherapy, whichever came first. In a situation in which patients' renal function was compromised, it was recommended that patients took a reduced dose of the trial drug, as levofloxacin is eliminated from the body mainly via excretion of unmetabolised drug in the urine by the kidneys. eGFR, provided locally, when possible, was assessed at baseline and reassessed at each scheduled trial visit to identify changes in renal function that would necessitate a change in dose of levofloxacin. It was recommended that eGFR was assessed within the 7- to 14-day period prior to randomisation. Those patients with an eGFR of > 50 ml/minute/1.73 m^2 took two tablets once per day (a dose of 500 mg), those patients with an eGFR of 20–50 ml/minute/1.73 m^2 took one tablet daily (a dose of 250 mg) and those patients with an eGFR of < 20 ml/minute/1.73 m^2 took a half-tablet daily (a dose of 125 mg). The active and placebo tablets were in identical breakable form. Dose reductions were recorded on the front of the patient diary, which was provided at each trial visit in conjunction with a review of eGFR.

Patients were asked to complete diaries during and after the 12-week treatment period, which were used to capture information related to drug compliance, health resource use and febrile episodes. Patients were asked

to take their temperature daily (at a similar time each day) using a digital oral thermometer provided by the co-ordinating centre. They were also asked to take and record their temperature at any time they felt unwell. If a temperature of ≥ 38 °C was recorded, they were encouraged to contact the hospital for assessment, whether or not antibiotic treatment was required. In the event of a febrile episode, it was suggested that patients remain on the trial drug and that management of infections should be as for an individual who was taking active levofloxacin. Patients were treated as per standard practice depending on the nature of the infection. On resolution of the infection, it was recommended that patients continue taking the trial drug. Any patient who had stopped taking the trial drug while being treated for an infection was asked to restart promptly on resolution of the infection. Any treatment breaks were recorded on the case report forms (CRFs) and excess tablets remaining as a result were returned to pharmacies for accountability purposes.

Supportive treatment

Supportive treatment practices common to each centre were allowed; this included the use of bisphosphonates, prophylactic antivirals and prophylactic *Pneumocystis* treatment. The use of prophylactic *Pneumocystis* treatment was discouraged and the use of nebulised pentamidine over oral co-trimoxazole (Septrin®, Actavis, Barnstaple, UK) was preferred. Other antibacterial prophylaxis was not allowed.

Central laboratory assessments

Microbiology assessments

Microbiological analysis was conducted at the Department for Medical Microbiology at St George's Hospital, London, and the Birmingham Public Health Microbiology (PMH) laboratory. Nasal swabs and stool samples were requested from patients at baseline (before the first dose of trial medication) and at 4, 8 and 12 weeks when receiving TEAMM treatment and again at 16 weeks. These were used to assess carriage of *S. aureus*, *C. difficile* and ESBL coliforms. Any toxigenic strains of *C. difficile* were identified by culture and ribotyping. Extended multilocus VNTR analysis typing will be performed on all isolates in the Birmingham PMH laboratory. ESBL-positive Gram-negative bacteria from faecal screens and clinical specimens (when available) were identified and sent to the Birmingham PMH laboratory for genotyping of CTX-M beta-lactamase genes using denaturing high-performance liquid chromatography. Nasal swabs were cultured for MRSA, and isolates were typed and stored. Cultures from invasive infections isolated locally were transferred to the central laboratory at St George's Hospital for typing when possible.

Immunology assessments

Immunology analysis was conducted by the Clinical Immunology Service at the University of Birmingham. Ethylenediaminetetraacetic acid (EDTA) blood, clotted blood and urine were requested from patients at baseline (before the first dose of trial medication) and at 4, 8 and 12 weeks when receiving TEAMM treatment and again at 16 weeks and 1 year. These samples were used to assess paraprotein levels, prognostic factors and markers of immunocompetence.

Measurements at entry and at 8 and 12 weeks included levels of:

- whole and free light chain (flc) paraprotein in serum and urine
- β_2-microglobulin, albumin, creatinine, calcium and C-reactive protein (CRP)
- complement components C3 and C4
- acute-phase response proteins and cytokines
- serum levels of polyclonal immunoglobulin (specific antibody against panels of both bacterial and viral antigenic targets and type I natural antibody levels)
- single-platform flow cytometric enumeration of lymphocyte subsets including type I and type 2 B cells, memory B cells; gamma/delta, cluster of differentiation 4 (CD4) and CD8 T cells; naive and memory subsets; Treg cells; and C cells
- monocyte subsets defined by CD14 and CD16 dendritic cells
- buffy coat cells, plasma and serum aliquoted and stored at –80 °C (not measured at 8 weeks).

Measurements at 4 and 16 weeks included levels of:

- whole and flc paraprotein in serum and urine
- β_2-microglobulin, albumin, creatinine, calcium, CRP response, markers of inflammation, and humoral and cellular immunocompetence.

The schedule of assessments is shown in *Table 1*.

Patient follow-up

Patients were followed up at approximately 4-week intervals during their 12 weeks of TEAMM treatment. They were seen again at 16 weeks and had a further follow-up at 1 year post TEAMM treatment start date.

Serious adverse events

Investigators were required to inform the WCTU about the occurrence of a SAE within 24 hours of becoming aware of the event. SAEs had to be reported if they occurred between the first dose of trial medication and up to 30 days after the last dose was taken. An AE was considered to be a SAE if one of the following conditions applied:

- results in death
- is immediately life-threatening
- requires hospitalisation or prolongation of existing hospitalisation
- leads to the development of any grade 4 non-haematological toxicity (excluding alopecia)
- results in persistent or significant disability or incapacity
- is otherwise medically significant (e.g. important medical events that may not be immediately life-threatening nor result in death or hospitalisation, but may jeopardise the patient or may require intervention to prevent one of the other outcomes listed above, excluding new cancers or result of overdose).

A serious adverse reaction (SAR) was defined as a SAE that has a definite, probable or possible causal relationship to levofloxacin. Causality was assessed by both a clinician at site and the chief investigator. SARs that were unexpected according to the summary of product characteristics for levofloxacin were considered to be suspected unexpected serious adverse reactions. For every AE symptom, an AE term and grade was applied by the site using the Common Terminology Criteria for Adverse Events (CTCAE) version 4.03.

The following SAEs were not required to be reported as they relate to myeloma and its treatment:

- disease progression
- disease-related deaths
- routine treatment or monitoring if the studied indication is not associated with any deterioration in condition
- treatment, which was elective or preplanned, for a pre-existing condition, not associated with any deterioration in condition
- general care not associated with any deterioration in condition
- treatment on an emergency outpatient basis for an event not fulfilling any of the definitions of 'serious' (as provided above) and not resulting in hospital admission
- hospitalisation for palliative care
- grade 4 haematological toxicity is an expected consequence of effective treatment and is required to be reported only if it fulfils the criteria of a SAE (as defined above)
- treatment (including hospitalisation or extension of hospitalisation) for transfusions or pain relief
- surgical interventions for skeletal-related events (e.g. fixation of fractures or vertebroplasty)
- skeletal-related events, including bone fractures, spinal cord compression and increased bone pain
- hypercalcaemia
- extravasation
- toxicities that meet serious criteria that developed prior to entry to the trial.

TABLE 1 Schedule of investigation

a The timing of viisits was flexible to allow them to coincide with chemotherapy visits as far as possible.

Patients who died on treatment or within 30 days of the last dose of treatment were reviewed separately by the chief investigator and by a consultant haematologist who was independent of the trial.

Patient withdrawal

It was made clear in the patient information sheet (PIS) that patients were free to withdraw at any point after consenting to take part without having to give a reason, and that withdrawal would not affect the standard of care they would receive. When the withdrawal reason was known, it was supplied to the trial office via the withdrawal form. Three different withdrawal options were given to maximise data collection and options were discussed with the patient when possible:

1. Patient withdrew from treatment only – this option meant that the patient continued on the trial with all active assessments other than administration of the trial drug.
2. Patient withdrew from treatment and assessments – this option meant that the patient did not complete any assessments or take an active role in the trial, but was happy for us to collect data about their disease status and standard treatment they were receiving. This will enable long-term follow-up to be conducted on these patients.
3. Patient withdrew consent – for these patients, no further data were collected or used in the analysis after the date of withdrawal. Data collected between the date of consent and the date of consent withdrawal have still been used unless specified by the patient.

Patients could also have been withdrawn from the trial at the discretion of the chief investigator and/or Trial Steering Committee if safety was a concern.

Patients moving out of area

When patients moved area and were no longer attending visits at the same centre, every effort was made to transfer the follow-up of patients to the new centre where their treatment was continuing. This was possible only if the new centre had the relevant approvals to participate in TEAMM.

Outcomes

Primary outcome measure: time to first febrile episode or death from all causes within 12 weeks of starting trial treatment

A febrile episode was identified and counted by a single oral temperature of $\geq 38\,°C$ (recorded either by a health-care professional or by the patient/carer, provided that the patient/carer had been trained and assessed as competent in temperature taking) and the patient was given anti-infectives.

A single febrile episode was defined as the initial febrile event and any subsequent fevers until that course of anti-infectives was stopped.

Capture of febrile episodes was via (1) documentation in hospital and (2) patient diary cards on which patients were asked to self-report temperature on a daily basis and at any time they felt unwell. Information gathered from documentation in hospital or in patient diaries was assessed every 4 weeks and translated onto on-treatment and infection CRFs.

Secondary outcomes

From start of trial treatment to 12 weeks

- Number of deaths and infection-related deaths: information on deaths was captured via notification of death and SAE forms.
- Number of days in hospital: information on hospital admissions was collected via SAE forms, on-treatment CRFs and follow-up CRFs.

- Number of days in hospital on anti-infectives: for each infection, a separate infection CRF was submitted, which collected all anti-infective treatment and any hospital admissions associated with the infection episode.
- Carriage and invasive infections with *S. aureus*, *C. difficile* and ESBL coliforms: nasal swabs and stool samples from patients were sent at 4-weekly intervals when on TEAMM treatment to the central microbiology laboratory. Samples were cultured to detect the presence of the organisms of interest.
- Patient characteristics, steroid usage and indices of immunocompetence and their relationship to colonisation by, and development of, infection from *S. aureus*, *C. difficile* and ESBL coliforms and non-HCAI and Eastern Cooperative Oncology Group (ECOG) performance status: CRFs at all time points collected information on performance status. Steroid information was captured on a treatment summary CRF that requested information about each antimyeloma treatment cycle. This was looked at in conjunction with the indices of immunocompentence, which resulted from the central immunology laboratory analysis of the blood and urine samples collected at all time points.
- Number of clinically documented total infections, episodes of severe sepsis (CTCAE grade 3 or 4) and suspected infections: febrile episodes (as defined above) and infections in which there was no associated fever (but which were treated with anti-infectives) were recorded on infection CRFs. Episodes of severe sepsis were captured via SAE forms.
- Incidence of microbiologically proven infections, the pathogens and their susceptibility to antibacterials: the infection CRF captured information about microbiological diagnosis and SAE forms prompted for microbiology reports to be sent to the trials office when there were positive microbiological cultures. Organisms' sensitivity profiles were usually present on local microbiological reports.
- Days on anti-infective treatment for treatment of infection: name and duration of treatment with each anti-infective were captured via infection CRFs.
- Response to antimyeloma treatment and its relationship to infection: response to antimyeloma treatment was looked at centrally using the blood and urine samples collected from patients. This information was looked at in relation to infections reported via infection CRFs.[29,30]

From start of trial treatment to beyond 12 weeks

- Carriage and invasive infections with *S. aureus*, *C. difficile* and ESBL coliforms between 12 and 16 weeks to assess for delayed effects from the intervention that was stopped at 12 weeks: organisms of interest were cultured from stool samples and nasal swabs that were taken at the 16-week time point (4 weeks post end-of-trial treatment).
- Response to antimyeloma treatment at 16 weeks. Because of the half-life of paraproteins, measurement of myeloma response cannot be undertaken until a minimum of 4 weeks after an intervention – blood and urine samples were sent to the central immunology laboratory for analysis at the 16-week time point, approximately 4 weeks after the treatment end date.
- QoL: the following validated questionnaires were used to assess QoL –

  o EuroQoL-5 Dimensions (EQ-5D)[31] – five-point scales and one 100-point summary scale (completed at all time points up to week 16)
  o European Organization for Research and Treatment of Cancer Quality of Life Questionnaire-C30 (EORTC QLQ-C30)[32] – five functional scales, three symptom scales and one global scale and six single items for assessment of general QoL (completed at all time points up to week 16)
  o European Organization for Research and Treatment of Cancer Quality of Life Questionnaire-24-item myeloma-specific module (EORTC-QLQ-MY24) – 24 questions covering disease symptoms, treatment side effects, body image and future perspectives of patients with multiple myeloma (completed only at baseline and week 12)
  o Hospital Anxiety and Depression Scale (HADS)[33] – a screening tool for anxiety and depression (completed at all time points up to week 16).

- Health economics: daily diary cards completed by patients captured elements of health resource use in combination with information captured on the CRF.
- Overall survival: captured via notification of death CRFs and flagging with the Office for National Statistics.

Sample size

The primary and first set of secondary outcomes were reached within 12 weeks of trial treatment. The primary outcome measure was time to first febrile episode or death from all causes, using a Kaplan–Meier survival curve. Assuming that the proportion of patients having a febrile episode or death was 30% in the first 3 months and that prophylactic antibacterials would reduce that rate to 20%, recruiting 800 patients into the trial (400 in each arm) would allow differences in excess of 10% to be detected with 90% power using a two-sided test at the 5% level of significance. Recruiting 1000 patients into the trial (500 in each arm) would allow differences in excess of 8% to be detected with 90% power using a two-sided test at the 5% level of significance. Recruiting 1000 patients would also allow detection of a levofloxacin-induced threefold increase in the rate of *C. difficile*-positive stools (from 5% to 15%) from entry to the trial to 12 weeks, with 95% power and 5% level of significance (two-sided test).

Other analyses include incidence of probable infections with site, severity and treatment; response to antimyeloma treatment and its relationship to infection; patient characteristics and indices of immunocompetence (blood leucocyte subset enumeration and antibacterial antibody titres) as prognostic markers for colonisation and invasive infection by antibiotic-resistant organisms; health economics; and QoL (by daily diary card and 4-weekly EQ-5D up to 16 weeks). With 1000 patients, it would be possible to report reliable estimates for these secondary outcomes.

Statistical methods

The main analysis, comparing time to first febrile episode or death from all causes within the first 12 weeks, was carried out using a log-rank comparison, with the start time being the date on which the patient started trial treatment to the time of a reported event, or to a censor date for those with no events reported after 12 weeks.[34] All randomised patients were included in the analysis of the primary end point as ITT using the date of randomisation as the start date for any patients not starting trial treatment.[35]

The secondary end points such as *C. difficile*-containing stools, MRSA and ESBL coliform carriage rates and number of invasive infections associated with the identical organism previously carried were assessed using chi-squared tests with continuity adjustments. Mantel–Haenszel tests for combining 2 × 2 tables were then used to adjust for stratification variables and various prognostic factors. Patients who were randomised and had started treatment were included in the analyses of the secondary end points.

Overall survival was calculated from the date on which the patient started trial treatment to the date of death or date of censorship, as appropriate. Overall survival analysis was based on all-cause mortality and assessed using Kaplan–Meier curves.[34] The main treatment effect was assessed using the log-rank test. Kaplan–Meier curves for the primary outcome were constructed for each treatment arm and Cox proportional hazards models were used to compare arms after adjustment for stratification variables and imbalances in important baseline factors.[34,36] Covariates were assessed graphically for non-proportionality of hazards. When there was an indication of non-proportionality, a time-dependent variable (its product with time) was introduced to test non-proportionality. If the Wald chi-squared *p*-value was < 0.05 for this term, then non-proportionality was assumed and a restricted mean survival time approach used with the test of the difference in restricted means presented instead of the hazard ratio (HR).[37,38] These analyses were carried out on an ITT basis.

The analyses of all other secondary end points, incidence of probable infections with site, severity and treatment, response to antimyeloma therapy and its relationship to infection and indices of immunocompetence (blood leucocyte subset enumeration and antibacterial antibody titres) were undertaken using the appropriate statistical analyses tools.

Statistical analyses were performed using SAS® version 9.4 (SAS Institute Inc., Cary, NC, USA). SAS and all other SAS Institute Inc. product or service names are registered trademarks or trademarks of SAS Institute Inc. in the USA and other countries. ® indicates USA registration.

Independent Data and Safety Monitoring Committee

An independent Data and Safety Monitoring Committee (DSMC) was established, consisting of an independent statistician, haematologist and microbiologist. Their main objective was to advise the Trial Steering Committee if there is evidence or reason why the study should be amended or terminated based on recruitment rates, compliance, safety or efficacy. The DSMC met after the first 50 patients were recruited, and annually thereafter. Confidential reports containing recruitment, protocol compliance, safety data and interim analyses of outcomes (not formally tested outside the trial statistical analyses plan, which was agreed with the DSMC) were reviewed by the DSMC. Interim analyses of the primary outcome were presented to the DSMC using conservative tests with significance determine by a *p*-value of 0.001 (to preserve the overall alpha level of 0.05). All analyses were blinded to the trial statistician and the DSMC until agreement to unblind at the end of the trial.

The original power calculations aimed to detect a difference of 10% (i.e. from 30% in the control arm to 20% in the treatment arm) with 90% power at the two-sided 5% level of significance. The first planned look at the primary end point when 150 patients had completed the 12-week assessment indicated that the original assumptions held true (i.e. a 31% rate in the control arm vs. a 21% rate in the treatment arm; documented in the DSMC December 2013 report). The prespecified look at the data before the trial recruitment closed (i.e. 760 patients recruited and 642 recruited patients having completed the 12-week assessment) indicated that the rate in the placebo arm may be reduced to 23% (note that this analysis remained blind to the treatment arm). After much discussion, the DSMC made recommendations to increase the sample size from 800 patients to up to 1000 patients (the maximum that could be accommodated by the available drug supply) within the current funding window. Increasing the sample size from the original 800 patients to up to 1000 patients allowed the power to be retained at 80% with the ability to detect differences in excess of 7% depending on the final rate in the control arm.

Database and data processing

The database was held on WCTU's Microsoft SQL Server (Microsoft Corporation, Redmond, WA, USA) system and imposed rules for data entry, which included having a valid range for responses, linked dates and patient identification (ID) numbers.

Data were single entered into the database by trial personnel. Checks were carried out on 100% of data entered by new starters and, following full training, 10% of data entered by trial personnel were checked each month. Unacceptable error levels in 10% checks were followed up with further checking and retraining. The trial statistician carried out checks of plausibility of values and missing data to enable further queries to be resolved prior to freezing data for scheduled analyses.

Chapter 3 Results

Screening and recruitment

Recruitment

A total of 977 patients were recruited between 3 August 2012 and 29 April 2016 from 93 NHS Hospitals (levofloxacin, *n* = 489; placebo, *n* = 488). *Figure 2* shows actual compared with target recruitment.

Two patients who were randomised withdrew consent on the day of randomisation and were withdrawn from further analyses as no data were collected. Twenty-five patients did not start trial treatment; baseline information was collected for 23 of these patients, and these patients are included in the analysis of the primary end point under ITT.

Screening

Sites were encouraged to screen all patients with newly diagnosed symptomatic myeloma to see if they were eligible. It was requested that all patients with whom the TEAMM trial had been discussed were recorded on the screening log provided. Sites were asked to record patient initials, date of birth, the date screening was initiated, if the patient consented and if they were subsequently randomised; in the case of patients who were not randomised, the sites were asked to provide a reason if possible. Screening logs were requested, on average, once every 6 months. More frequent requests were not necessary because of successful recruitment throughout. A final request was made for screening data after recruitment ended in April 2016. In total, 76 out of the 93 sites returned some screening data. *Appendix 1* shows the sites not wishing to participate (see *Table 40*), the number of patients screened at each site (see *Table 41*) and the most common reasons for screening failures (see *Table 42*). A total of 2183 potential patients were screened on the basis of the data available on the returned screening logs; of these, 977 (45%) went on to be randomised.
FIGURE 2 Cumulative recruitment.

Of the 1206 patients who were unable to be consented and randomised into the trial, the majority were found to be ineligible as a result of being outside the 14-day window for starting the TEAMM medication after the start of their antimyeloma treatment. This was a problem when patients had started a steroid treatment for their myeloma prior to commencing full cycles of chemotherapy. Of the remaining patients, 278 declined to take part without providing a detailed reason as to why. When explanations were provided, the most common reason for declining to participate was that patients had too much going on in their lives. With a new diagnosis of myeloma, many patients being elderly and having other comorbidities, patients felt that taking tablets and temperatures and completing a diary were too much to cope with. Other common reasons were not wanting to take part in a clinical trial or not wanting to take part in more than one trial as many were also eligible for other complementary myeloma trials.

Recruitment by centre across treatment arms
Table 2 shows the final number of patients recruited from each of the 93 centres, by treatment arm.

Withdrawals
Table 3 lists the three levels of withdrawal from the trial and the reasons for withdrawal within those groupings. Of the patients who withdrew, 32% withdrew from treatment but agreed to continue with all trial-related activities with full data collection, 36% were happy for us to collect long-term health and survival data from them but did not want to continue with any trial-related activities and 31% withdrew their consent for us to collect any further information regarding them or their condition. As a minimum, even for withdrawn patients, baseline data were collected for all patients when possible.

TABLE 3 Withdrawals, by treatment arm

| Withdrawal status | Reason for withdrawal | Treatment arm, *n* (%) | | Total, *n* (%) |
		Levofloxacin	Placebo	
Ceased treatment but remained on follow-up as per protocol (*N* = 73, 32%)	Suspected trial drug toxicity	21 (54)	11 (32)	32 (44)
	Participant decision	8 (20.5)	10 (29)	18 (25)
	Other reason	10 (26)	13 (38)	23 (31.5)
Withdrawn from treatment and assessments (*N* = 82, 36%)	Suspected trial drug toxicity	6 (13)	9 (24)	15 (18)
	Participant decision	24 (53)	18 (49)	42 (51)
	Other reason	15 (33)	10 (27)	25 (30)
Withdrawn consent for further data to be collected (*N* = 71, 31%)	Suspected trial drug toxicity	5 (14)	5 (14)	10 (14)
	Participant decision	19 (53)	23 (66)	42 (59)
	Other reason	12 (33)	7 (20)	19 (27)

Unblinding by treatment arm

The unblinding service was contacted regarding TEAMM patients on 29 occasions: 14 of the calls, after further discussion, did not result in the treatment allocation being unblinded, and 15 of the calls resulted in the treatment allocation being unblinded to the caller (two of the calls were redirected to a more appropriate service). Examples of situations in which patients' treatment allocation was unblinded included tendonitis/tendon rupture, unexpected deterioration in kidney or liver function, confusion, suspected Stevens–Johnson syndrome and unexplained neurological symptoms.

Data return

Data were locked on 24 April 2017. *Table 4* reports the number of CRFs returned and expected at the time of analysis.

Consolidated Standards of Reporting Trials flow diagram

The Consolidated Standards of Reporting Trials (CONSORT) flow diagram is shown in *Figure 3*.

Baseline characteristics

Stratification factors of participants by treatment arm

Treatment allocation by minimisation was balanced by site, eGFR on entry into the trial and intention to give high-dose chemotherapy with autologous stem cell transplant, as shown in *Table 5*.

Baseline characteristics of participants by treatment arm

Baseline characteristics were well balanced across treatment arms, as shown in *Table 6*.

Disease characteristics at presentation were also well balanced, as shown in *Table 7*.

TABLE 5 Randomisation, by treatment arm

Protocol deviations/non-compliance

One patient was retrospectively found not to be eligible because they were found to have multiple plasmacytoma and not myeloma when further results came to light. A total of 24 patients were, at some point during their treatment, taking the incorrect dose on the basis of their eGFR result. Among this group, clinician decisions not to increase the dose based on patients' conditions are classed as deviations. The remainder of instances of non-compliance were down to site errors or patient confusion. Details of the type of non-compliances are shown in *Table 8*.

Protocol deviations are shown in *Table 9*. A number of patients did not take the TEAMM medication for the correct number of days as stated in the protocol (84 days), some took it for fewer days than expected and some took it for more days than was stated. Those who took TEAMM treatment for fewer days than expected were required to note this either in a withdrawal form or on the on-treatment form as missed treatment. Patients who took the trial medication for more than the 84 days of treatment misunderstood the trial procedure and continued to take remaining tablets as a result of treatment breaks or dose reductions. Patients taking trial treatment for up to 98 days were not classed as non-compliers as it was felt that the data would not be significantly affected by this. The remaining patients who took trial treatment for > 98 days were classed as protocol violations. There were 13 patients who failed to begin their randomised treatment within the 14-day eligibility window stated in the protocol. All of these patients were eligible at the time of randomisation and all violations resulted from a change in the patient's circumstances that resulted in the anticipated start date changing to one outside the 14-day window. These non-compliances are balanced by treatment arm, as shown in *Table 9*.

TABLE 8 Reported non-compliance

	Non-compliance	
Type of protocol non-compliance	Violations (*n*)	Deviations (*n*)
Failure to report SAE	13	0
Incorrect dose on basis of eGFR: lower dose than protocol stated	13	6
Incorrect dose on basis of eGFR: higher dose than protocol stated	5	0
Failure to start TEAMM medication within 14 days of antimyeloma treatment	5	8
Continued treatment past the 84-day period stated in the protocol	11	0
Stool sample taken after first dose of TEAMM medication	0	1
Retrospectively found not to be eligible	1	0
Incorrect pack number dispensed	2	0
Prescription and administration of a contraindicated drug	5	1
Patient incorrectly told to stop taking trial drug before 12-week time point	1	0
Total	56	16

TABLE 9 Protocol deviations, by treatment arm

	Treatment arm, *n* (%)		Total (*N* = 925),
Non-compliance	Levofloxacin (*N* = 468)	Placebo (*N* = 457)	*n* (%)
Taken for > 98 days	7 (1)	4 (1)	11 (1)
Started > 14 days of starting antimyeloma treatment	7 (1)	6 (1)	13 (1)
Lower dose	10 (2)	9 (2)	19 (2)
Higher dose	3 (< 1)	2 (< 1)	5 (< 1)

Treatment data across 12 weeks

Data were captured on participants while on treatment at 4, 8 and 12 weeks. At the time of data lock, a total of 2599 treatment forms had been returned by 925 patients. *Table 10* presents on-treatment information by treatment arm.

The treatment information for the entire treatment period (from 0 to 12 weeks) is summarised in *Table 11*.

a One episode of diarrhoea on the placebo arm was microbiologically proven to be *C. difficile*.

Infections

Febrile episodes

Table 12 presents the number of febrile episodes experienced by treatment arm. A total number of 264 febrile episodes were reported, with 113 episodes of these being reported by patients in the levofloxacin arm, compared with 151 in the placebo arm. The number of patients reporting febrile episodes was consistently higher in the placebo arm.

TABLE 12 Total number of reported febrile episodes, by treatment arm

1	74 (16)	104 (22)	178 (19)
2+	18 (4)	21 (5)	39 (4)
p-trend = 0.02			
Number of patients reporting infections	92	125	217
Total number of episodes	113	151	264

There was a significant trend in the number of febrile episodes reported across treatment arm within the 0- to 12-week summary (Mantel–Haenszel χ = 5.52; *p* = 0.02), with more febrile episodes reported in the placebo arm. This difference can be explained by the number of febrile episodes reported within the 4- to 8-week period from starting the trial treatment (*p* = 0.03).

There were 264 febrile episodes reported, for which infection forms were returned. Details on the site, type and confirmation of infections are detailed in *Table 13*.

a There were 14 'other' reported sites of febrile infections: seven in the levofloxacin arm and seven in the placebo arm. The seven febrile infections reported in the levofloxacin arm were suspected meningitis; acute kidney infection; diverticular abscess; generalised myalgia, possibly viral; hospital-acquired pneumonia and hospital-acquired kidney injury, both on diagnosis; reaction to either allopurinol or thalidomide; and an intraoperative tear during spinal surgery, in which the patient's temperature spiked after surgery, an infection was suspected. The seven febrile infections reported in the placebo were neutropenic sepsis (two patients), neutropenic sepsis and anaphylaxis-type reaction, neutropenic sepsis allergic reaction to medication, acute cholecystitis, fever and atrial fibrillation, and testicles.

Other (non-febrile) infections

There were 249 patients who reported to have suffered a non-febrile infectious episode; there were 116 in the levofloxacin arm, compared with 133 patients in placebo arm (*Table 14*). A total of 323 episodes were reported (144 in the levofloxacin arm vs. 179 in the placebo arm).

There was a borderline trend in the number of non-febrile infections reported across treatment arms within the 0- to 12-week summary (Mantel–Haenszel $\chi = 3.67$; $p = 0.06$), with more episodes reported in the placebo arm.

At the time of data lock, 323 infection forms reporting details of non-febrile episodes had been received: 144 from the levofloxacin arm and 179 from the placebo arm. Details of these non-febrile episodes reported on the infection forms are summarised in *Table 15*.

a There were 42 'other sites of clinically diagnosed infections': 17 in the levofloxacin arm and 25 in the placebo arm. The 17 infections reported in patients in the levofloxacin arm were eye infection (two patients), oral thrush (two patients), intra-abdominal abscess (two patients), pelvic abscess (two patients), cellulitis/orbital cellulitis (two patients), sinusitis, tickly cough – possible chest infection, vaginal candidiasis, bilateral pedal oedema overlying skin blisters and ulcers, no-infection-treated hyponatraemia, pain in right ear and jaw and poorly controlled AF and opiate excess. The 25 infections reported in the placebo group were eye infection/conjunctivitis (eight patients), mouth/oral thrush (five patients), sinusitis/ear infection (four patients), shingles (three patients), blepharitis, cardiac (endocarditis), *Haemophilus influenzae*, peripheral nerve infection and suspected cellulitis (recorded by an out-of-hours GP) on the right lower leg – later confirmed as deep-vein thrombosis.

Total infections

A total of 411 patients reported an infection (febrile or non-febrile) on their on-treatment form (190 in the levofloxacin arm and 221 in the placebo arm). A total of 587 infectious episodes were reported (257 in the levofloxacin arm and 330 in the placebo arm), as shown in *Table 16*.

3+	14 (3)	24 (5)	38 (4)
p-trend = 0.005			
Number of patients reporting infections	190	221	411
Total number of infections	257	330	587

There was a significant trend in the total number of infections reported across treatment arms within the 0- to 12-week summary (Mantel-Haenszel χ = 7.89; *p* = 0.005), with more patients reporting total infections in the placebo arm. This difference can be explained by the number of infections reported per patient between the 4- to 12-week period from starting trial treatment.

At the time of data lock, 587 infection forms reporting details of these episodes had been received: 257 from patients of the levofloxacin arm and 330 from patients of the placebo arm. Infection details are shown in *Table 17*.

Incidence of microbiologically proven infections, the pathogens and their susceptibility to antibacterials

The identity of species cultured from invasive isolates were extracted from laboratory reports of the 112 specimens. The laboratory reports were obtained for patients in which positive cultures were detected; of the 131 patients reported with positive cultures, 49 were reported in the levofloxacin arm and 82 were reported in the placebo arm (*Table 17*). A total of 112 organisms were detected: 44 from the levofloxacin arm and 69 from the placebo arm. There were fewer Gram-negative infections reported in the levofloxacin arm than in the placebo arm (*Table 18*).

Cephalosporin	2/2	100	6/8	75	
Other	34/44	76	62/83	75	

Deaths and infection-related deaths

Overall, a total of 116 deaths were reported among the 977 randomised patients (levofloxacin, $n = 61$; placebo, $n = 55$). A total of 30 patients (total of 52 causes) died within 12 weeks of starting trial treatment (levofloxacin, $n = 8$; placebo, $n = 22$). One patient randomised to placebo died prior to starting trial treatment. A total of 86 patients died post 12 weeks (levofloxacin, $n = 53$; placebo, $n = 33$). *Table 20* presents causes of death by treatment arm. A total of 220 causes of death were reported for the 116 deaths, as selection of multiple causes is permitted on the death form. Cause of death was not available for one patient on placebo who died in a nursing home.

TABLE 20 Causes of death, by treatment

	Other	11 (9)	6 (6)	17 (8)
	Subtotal	41 (35)	36 (35)	77 (35)

The majority of deaths were attributed to myeloma-related causes (*n* = 143, 65%) as opposed to non-myeloma-related causes (*n* = 77, 35%). Infection-related cause of death was less common in the levofloxacin arm (three causes) than in the the placebo arm (eight causes) within 12 weeks. However, more infection-related causes of death were reported in the levofloxacin arm (19 causes) than in the placebo arm (12 causes) post 12 weeks.

All deaths within 12 weeks were reviewed by an independent clinician to ascertain causes of death. Deaths post 12 weeks were reviewed by the two clinical chief investigators.

Time to first event by treatment arm across 12 weeks

Table 21 shows the number of febrile episodes, deaths and febrile episodes and deaths combined by treatment arm within the first 12 weeks. A total of 210 patients reported febrile infections (levofloxacin, *n* = 91; placebo, *n* = 119) out of the total 977 patients randomised.

Time to first event was calculated from the date of starting trial treatment to the date of febrile episode or date of death for the 229 patients reporting a febrile episode or death within 12 weeks. The remaining patients were censored at date of withdrawal or the last date considered appropriate. *Figure 4* shows the 19% of patients randomised to levofloxacin reporting a febrile episode, or death, within 12 weeks from the start of trial treatment compared with the 27% in the placebo arm; log-rank χ^2 test = 9.78; HR 0.66, 95% CI 0.51 to 0.86; *p* = 0.002 in favour of levofloxacin.

TABLE 21 Combined events (febrile episodes and deaths), by treatment arm

Event category	Treatment arm, *n* (%)

Placebo	488	444	408	393	375	364	348	340	332	324	317	310	303
FIGURE 4 Time to first event (febrile or death) within 12 weeks. Log-rank χ^2 test = 9.78; HR 0.66, 95% CI 0.51 to 0.86; p = 0.002.

The Cox regression analysis showed that treatment is the most important factor and still retains significance in a multivariate model adjusting for baseline factors. A Cox regression model excluding treatment indicates that no other factors predict time to febrile episode or death. Assessing the individual factors indicates that ECOG performance status is the only factor with a borderline significance. *Table 22* shows the treatment effect unadjusted and adjusted by baseline factors. It can be seen that adjustment makes little difference to the overall treatment effect.

TABLE 22 Cox regression to predict febrile episode or death within 12 weeks of starting trial treatment

Factor	Grouping	Coefficient	*p*-value	HR (95% CI)
Treatment only (*n* = 977; 229 events)				
Treatment	Placebo, levofloxacin	−0.42	0.002	0.66 (0.51 to 0.86)
Treatment adjusted for baseline factors (*n* = 668; 166 events)				
Treatment	Placebo, levofloxacin	−0.32	0.04	0.73 (0.53 to 0.99)

Vertebral (*n* = 977, events = 229)	Absent, present	0.02	0.90	1.02 (0.76 to 1.36)
ESBL isolated at baseline (*n* = 785, events = 187)	No, yes	0.39	0.06	1.49 (0.98 to 2.27)
Neutrophils (*n* = 967, events = 229)	Continuous	−0.02	0.37	0.98 (0.94 to 1.02)
Prophylactic Septrin (*n* = 946, events = 224)	No, yes	−0.52	0.0008	0.59 (0.44 to 0.80)

TABLE 22 Cox regression to predict febrile episode or death within 12 weeks of starting trial treatment (*continued*)

Factor	Grouping	Coefficient	*p*-value	HR (95% CI)
Anti-infective history (treatment of infection month prior to trial treatment) (*n* = 814, events = 182)	No, yes	0.36	0.04	1.43 (1.01 to 2.01)
Steroids in 14 days prior to randomisation (*n* = 970, events = 229)	No, yes	−0.09	0.52	0.92 (0.71 to 1.19)
Treatment and prophylactic Septrin (*n* = 946, events = 224)				
Treatment	Placebo, levofloxacin	−0.41	0.002	0.66 (0.51 to 0.86)
Prophylactic Septrin	No, yes	−0.52	0.0009	0.59 (0.44 to 0.81)

The most significant individual baseline factor was the use of prophylactic Septrin (HR 0.59, 95% CI 0.44 to 0.80; *p* = 0.0008), followed by treatment (HR 0.66, 95% CI 0.51 to 0.86; *p* = 0.002). Adjusting treatment for prophylactic Septrin use made little difference to the treatment effect, indicating that these two variables have independent prognostic value (*Figure 5*).
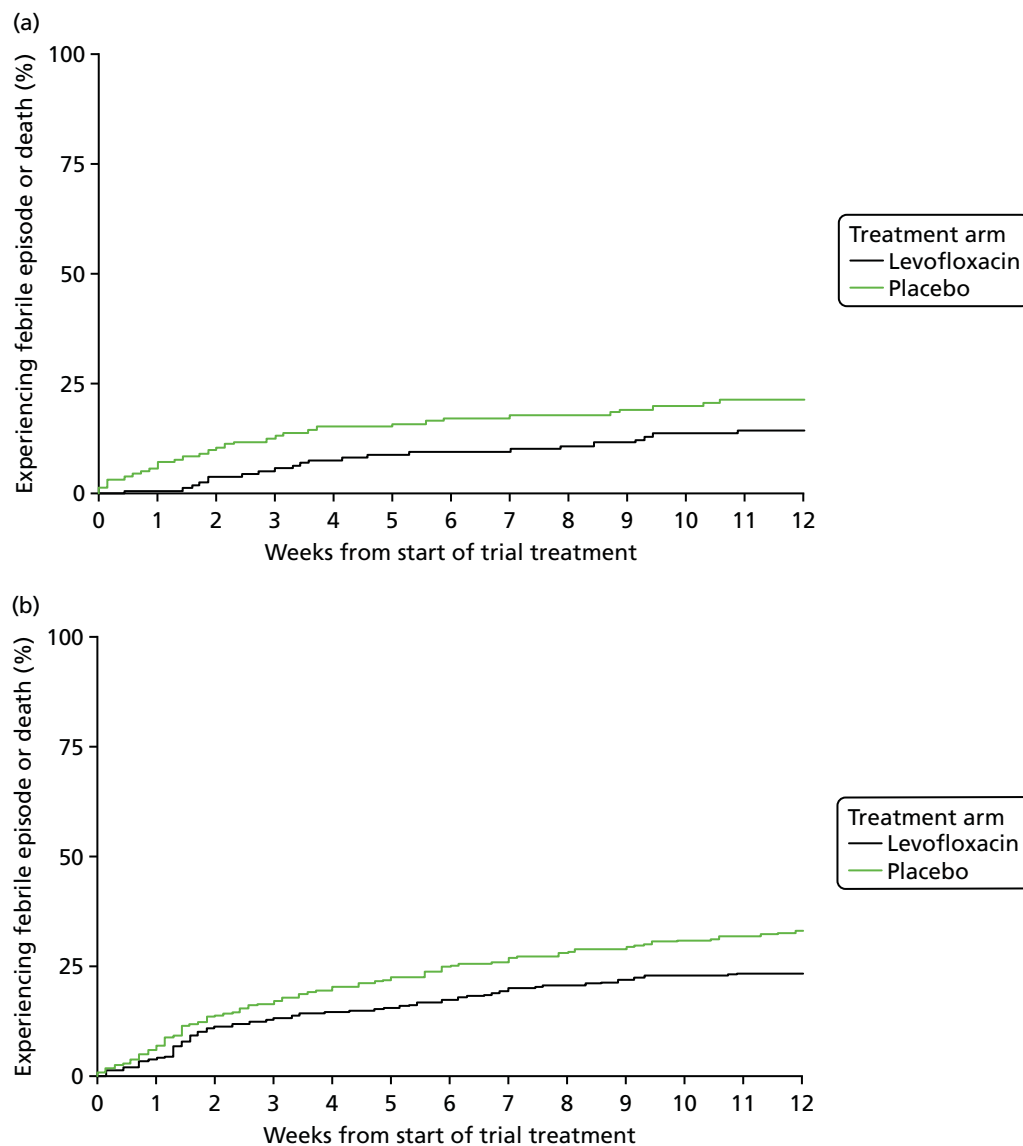

FIGURE 5 Treatment adjusted for Septrin (*p* = 0.002). (a) Septrin; and (b) no Septrin.

44

Overall survival

Overall survival was calculated from the date of starting trial treatment to the date of death or being censored at date last alive. *Figure 6* shows that 98% of patients on levofloxacin survived for 12 weeks, compared with 95% of patients on placebo ($p = 0.94$). Twelve-month survival was similar across arms (levofloxacin, 90%; placebo, 91%). Follow-up of surviving patients was the same [median 12 months; interquartile range (IQR) 11–13 months] in both arms.

	0	1	2	3	4	5	6	7	8	9	10	11	12
Levofloxacin	489	461	439	426	401	380	374	371	368	363	359	356	342
Placebo	488	446	420	405	393	378	373	373	371	370	369	365	356
FIGURE 6 Overall survival, by treatment. Log-rank χ^2 test $= 0.004$; $p = 0.94$.

Micro-organism sample return and acquisition

Table 23 shows the numbers of *C. difficile*, MRSA and ESBL Gram-negative organisms that were present at baseline. It also shows the number of new acquisitions between baseline and 16 weeks. The total number of nasal and stool samples returned between baseline and 16 weeks is indicated in the left-hand column. There were no differences in new ESBL acquisitions between the placebo and levofloxacin arms (30 vs. 25, respectively). There were no differences in acquisitions for *C. difficile* (8 vs. 11) and MRSA (7 vs. 4) between the placebo and levofloxacin arms.

Days on additional anti-infective treatment and total doses taken for treatment of infection, by treatment arm

A summation of all anti-infective drugs prescribed for the treatment of infections during the trial treatment period by treatment arm, excluding TEAMM trial medication, is shown in *Table 24*.

Response to antimyeloma treatment

Response to myeloma treatment within the first 12 weeks is an early indication of whether or not patients will reach stable disease. The main reason why patients do not respond is disease progression. Changes between blood samples collected at baseline and the last sample collected within 12 weeks will indicate if patients have had an early response to antimyeloma treatment. This will be presented as part of the TEAMM National Institute for Health Research (NIHR) Efficacy and Mechanism Evaluation (EME) grant (reference number 14/24/04).

Serious adverse events

Since the start of the trial, a total of 597 SAEs have been reported to the TEAMM trial office (of these, 308 were from patients on levofloxacin and 289 were from patients on placebo). *Tables 25–28* present information relating to the type of event by treatment for all SAEs and summarises the severity and causality assessments, and outcomes of each event by treatment.

TABLE 25 Event type, by treatment arm

Event type	Treatment arm, *n* (%)		Total, *n* (%)

Consent withdrawn prior to resolution	1 (0.3)	0 (0)	1 (0.2)

In summary, 597 SAEs were reported for patients (levofloxacin, n = 308; placebo, n = 289), with the majority reported as being unlikely to be related to or unrelated to the study drug (537/597, 90%) but, instead, related to hospitalisation or prolongation of existing hospitalisation (462/597, 77%). Toxicity reported to be related to levofloxacin (38 episodes) compared with placebo (22 episodes) had a trend towards more gastrointestinal disorders (fours events of nausea/vomiting on levofloxacin vs. one event on placebo) but fewer episodes of diarrhoea (five episodes on levofloxacin vs. nine episodes on placebo), rash (six episodes on levofloxacin vs. one episode on placebo), psychiatric disorders (two episodes on levofloxacin vs. no episodes on placebo) and musculoskeletal and connective tissue disorders (seven episodes on levofloxacin and one episode on placebo) (see *Table 44*). *Appendix 2* provides further information as regards the summary of the CTCAE categories of all SAEs reported (see *Table 43*) together with their terms of SAEs by treatment (see *Table 43*). In addition, reported SARs are detailed (see *Tables 44* and *45*).

Quality of life

Within the scope of the TEAMM grant, QoL was measured at baseline and at 4, 8, 12 and 16 weeks for patients who consented to fill in the QoL booklets. These data include the responses to the EQ-5D, which are reported in *Chapter 4*, as well as to the EORTC QLQ-C30, EORTC QLQ-MY24 and HADS.

Chapter 4 Health economic analysis

Introduction

An economic evaluation was conducted to estimate the cost-effectiveness of prophylactic levofloxacin compared with placebo in newly diagnosed symptomatic myeloma. The economic evaluation was conducted alongside the TEAMM clinical trial so that only the data collected during the trial were analysed. Cost and outcome data were collected from trial participants for 16 weeks. However, if the intervention is successful in reducing mortality, the benefits may extend beyond this period. Consequently, the economic evaluation includes a within-trial cost-effectiveness analysis over 16 weeks but also explores longer-term outcomes using an analysis extrapolated to 12 months from randomisation.

Methods

Aim and end points

The primary aim of this analysis was to assess the cost-effectiveness of antibiotic prophylaxis using levofloxacin alongside antimyeloma therapy compared with using placebo alongside antimyeloma treatment in patients with newly diagnosed symptomatic myeloma. The primary end point was the cost per quality-adjusted life-year (QALY) gained at 16 weeks. The methods used for this within-trial analysis were guided by the recommendations of the National Institute for Health and Care Excellence (NICE) methods guide.[39]

Perspective and time frame

The trial adopted a health-care and Personal Social Service provider perspective. Direct costs and outcomes of patients randomised to levofloxacin versus placebo were compared over the 16-week time horizon of the trial. As the time frame of the trial was < 1 year, discounting of the costs and benefits was not required.

Measurement of outcomes

Primary outcome

This analysis used the QALY as the main outcome measure. QALYs are a generic measure of health that take account of both the quality and length of life, such that 1 QALY is equal to 1 year of life lived in a state of full health.[40]

Health state utility values were obtained from patient responses to the EQ-5D three-level version questionnaire,[31] which was administered at baseline and at weeks 4, 8, 12 and 16 post randomisation. The EQ-5D is a commonly used generic measure of health-related quality of life (HRQoL) and NICE's[39] preferred outcome measure for cost-effectiveness analysis. Patient responses were converted to utility values using the standard UK general population time trade-off tariff values.[41] The utility values represent patients' QoL and were multiplied by duration (t) in each health state to generate QALYs. An area under the curve approach was adopted for estimating QALYs with a linear transition assumed between adjacent time points:

$$QALY = \{[(EQ\text{-}5D_{baseline} + EQ\text{-}5D_4)/2] \times t\} + \{[(EQ\text{-}5D_4 + EQ\text{-}5D_8)/2] \times t\} + \{[(EQ\text{-}5D_8 + EQ\text{-}5D_{12})/2] \times t\} + \{[(EQ\text{-}5D_{12} + EQ\text{-}5D_{16})/2] \times t\},$$

(1)

where $EQ\text{-}5D_{baseline}$, $EQ\text{-}5D_4$, $EQ\text{-}5D_8$, $EQ\text{-}5D_{12}$ and $EQ\text{-}5D_{16}$ are the EQ-5D scores at baseline, week 4, week 8, week 12 and week 16, respectively. If an individual died during the trial, it was assumed that their utility value was 0 from the date of death to trial end and assumed a linear transition to this value from their last completed EQ-5D.

The EORTC QLQ-C30 was also administered alongside the EQ-5D questionnaire at each trial follow-up. QALYs were calculated using the EORTC-8D as a sensitivity analysis in order to examine the effect of using a disease-specific measure of HRQoL compared with a generic measure (EQ-5D).[32]

Total QALYs were calculated for each patient over the 16 weeks and summary statistics were generated by intervention group. Differences between groups were compared using independent-sample *t*-tests.

Secondary outcome

A secondary outcome measure considered in the analysis was number of febrile episodes. This is the primary outcome measure for the clinical analysis and allowed a useful complementary economic analysis of the cost per febrile episode avoided. Details of febrile episodes were collected in clinic visits at the start of trial treatment and then every 4 weeks until the end of treatment in week 12.

Measurement of resource use

All health-care resource use was estimated from the perspective of the health-care and Personal Social Service provider and was collected for the trial period of 16 weeks from randomisation. This included primary care such as GP visits and nurse home visits as well as secondary care such as outpatient visits and other hospital admissions. At 12 months, data were limited to the number of hospital admissions and associated length of stay between 16 weeks and 12 months.

Resource use was captured using three complementary approaches of data collection within the trial: (1) patient diaries, (2) trial CRFs and (3) hospital data. Patients completed diaries of resource use, which they brought with them to follow-up visits. Nurses used the patient diaries to summarise resource use on the CRFs following discussions with patients, at which time corrections to the resource use were made. Hospital data reporting admissions were also collected, which were used alongside patient-reported resource use.

As multiple sources of data were used to capture resource use, there was potential for discrepancies between the sources in the resource use recorded for any given patient. For example, the number of hospital visits recorded on hospital systems may differ from the number recalled by patients. When there were discrepancies between data sources, it was assumed that hospital records were more reliable and these data were given precedence. In order to test the effect of this assumption, sensitivity analyses were conducted using the data from patient recall.

Cost analysis

All resource use data were converted to costs using appropriate UK unit costs estimated at the time of analysis. Unit costs were assigned to health-care resource use from the *British National Formulary* (BNF),[42] Personal Social Services Research Unit's (PSSRU) *Unit Costs of Health and Social Care* 2015[43] and the Department of Health and Social Care's *NHS Reference Costs 2014 to 2015*.[44] Costs were assigned on a per-unit basis with unit values taken from the resource use data collected within the trial (i.e. from patient diaries, CRFs and hospital data). All inpatient and outpatient hospital stays or use of community health and social services that occurred within the trial period were costed irrespective of whether or not their use was directly associated with the treatment of myeloma. Unit costs for the main resource use items (those specified on the resource use CRF) are presented in *Table 29*, together with the costing of the treatment medications. In addition to those resource use items specified in the form, patients were also given a free-text box to enter other items of resource use. These items were costed individually, and full unit costs, including those used to cost additional resource use items recorded, are outlined in *Appendix 3* (see *Tables 45–47*).

Patients' use of health-care resources and total costs were calculated for the ITT population. Total costs for each patient were calculated as the sum of costs assigned for hospital, community health and social services and medication use.

TABLE 29 Unit costs for main resource use items

Resource item	Unit cost (£)	Source	Details
Trial medication			
Levofloxacin, 250 mg	11.57 per 10-tablet pack	BNF 2017	Normal dose: two tablets per day
			Moderate renal failure: one tablet per day
			Severe renal failure: half-tablet per day
Levofloxacin, 500 mg	11.40 per 10-tablet pack	BNF 2017	
Community health and social services			
GP visit, surgery	36.00 per visit	PSSRU 2016, p. 145[45]	GP, per patient contact lasting 9.22 minutes, including direct care staff costs
District nurse visit	38.00 per visit	*NHS Reference Costs 2015 to 2016*[46]	District nurse, adult, face to face
			CC: N02AF; SC: NURS
Home help or care worker visit	24.00 per visit	PSSRU 2016, p. 160[45]	Face-to-face 1-hour weekday session
Hospital-based or residential care services			
Hospital inpatient	298.41 per day	*NHS Reference Costs 2015 to 2016*[46]	Total Healthcare Resource Groups, average of all non-elective inpatient excess bed-days
Hospital critical/intensive care unit	521.00 per day	*NHS Reference Costs 2015 to 2016*[46]	Medical adult patients (unspecified specialty), adult critical care, zero organs supported, CC: XC07; SC: CCU03
Hospital outpatient	135.00 per visit	PSSRU 2016, p. 95[45]	Weighted average of all outpatient attendances
A&E	137.74 per visit	*NHS Reference Costs 2015 to 2016*[46]	Emergency medicine, average unit costs of all emergency medicine attendances
Residential home	90.00 per day	PSSRU 2016, p. 26[45]	Private sector residential home cost per permanent resident day

A&E, accident and emergency; CC, currency code; SC, service code.

Adjusting for baseline imbalance

Using a randomised controlled study design means that the baseline and socioeconomic characteristics of groups being compared should be well balanced. However, despite randomisation, there will inevitably be some differences in mean baseline values between groups. This is of particular importance because a patient's utility at baseline is likely to be correlated with their utility over the follow-up period. Therefore, the imbalance in baseline utilities needs to be accounted for when calculating the differential effects between treatment arms.[47,48] Multiple regression analysis was used to estimate differential mean QALYs and to predict adjusted QALYs controlling for utility at baseline.

Missing data

In economic analyses conducted alongside clinical trials, incomplete or missing data are inevitable. Based on descriptive analysis of the missing data, the analysis was conducted under the assumption that the missing data were missing at random (MAR). Analysis of the number of missing data by trial group at each follow-up and visual analysis of missing data patterns indicated that the data were unlikely to be missing completely at random as the proportion of missing data differed by time point (although the proportion of data missing did not differ by treatment allocation).[49] This was explored further using logistic regression to investigate which factors were associated with the probability of missing data. This indicated that MAR may be a plausible assumption under which to conduct the analysis. However, it was noted that it is difficult to rule out missing not at random because the unobserved data are unknown. Consequently,

when there were missing data, multiple imputation methods were used to generate estimates of missing values based on the distribution of observed data. The multiple imputation approach is the recommended method of imputation for economic evaluation alongside clinical trials as it includes randomness to reflect the uncertainty inherent in missing data by using iterative multivariable regression techniques.[50]

When choosing the level at which to impute missing data (more or less aggregated), a balance needs to be struck between maintaining the data structure and achieving a stable imputation model.[49] Consequently, for QoL data, missing EQ-5D index values were imputed at each follow-up. For costs, missing data were imputed at the level of total health and social services costs, total hospital costs and total treatment costs, not at the unit of resource level. EQ-5D index values were recorded as missing if any EQ-5D items were missing. Missing baseline EQ-5D values were imputed using mean imputation to ensure that imputed values were independent of the treatment allocation.[51] Missing EQ-5D scores at the remaining follow-ups were imputed using multiple imputation methods. Costs were counted as missing if all resource use items on the CRF were missing and missing cost data were imputed at each follow-up using multiple imputation methods.

The imputation was performed in Stata® version 14 (StataCorp LP, College Station, TX, USA) using predictive mean matching to perform multiple imputation by chained equations. Predictive mean matching ensures that only plausible values of the missing variable are imputed as the imputed value is drawn from another individual whose predicted value is close to the predicted value of the individual with the missing observation.[49]

Cost-effectiveness analysis

Primary analysis
The cost-effectiveness analysis adopted an ITT perspective for analysing and summarising the health economic trial data. The primary analysis consisted of a cost–utility analysis over the 16-week trial period and included adjustment for baseline variables and imputation of missing data. The incremental cost per QALY gain as a result of the use of levofloxacin compared with placebo was calculated. This was calculated by dividing the mean difference in cost of the two treatment arms by the mean difference in QALYs to produce an incremental cost-effectiveness ratio (ICER), as follows:

$$ICER = (Cost_A - Cost_B)/(QALY_A - QALY_B). \tag{2}$$

The ICER represents the additional cost per QALY gained for each intervention compared with the next best alternative.[52] NICE[39] considers a cost per QALY within the range £20,000–30,000 to be acceptable. The lower limit of this threshold ($\lambda = £20,000$) was used to determine cost-effectiveness. Interventions with an ICER < £20,000 per QALY gained are generally considered cost-effective.

Secondary analyses
The secondary analyses included a cost-effectiveness analysis, in which the cost per febrile episode avoided attributable to antibiotic prophylaxis compared with placebo was calculated. This analysis was conducted in a similar way to the primary analysis; however, as data on febrile episodes were collected only over the treatment period (baseline to 12 weeks), the time horizon for this analysis was 12 weeks, rather than 16 weeks (as was used in the primary analysis). In addition, a cost–utility analysis was conducted over a 12-month time horizon.

Sensitivity analysis
Alternative scenarios were explored in the sensitivity analysis to test the robustness of the main trial analysis results. The effect of not imputing missing data was considered with an analysis including only complete cases. In addition, the effect of adjusting for baseline imbalance on cost-effectiveness was explored using an analysis with no adjustment for baseline differences between groups. Further sensitivity analyses were conducted to explore the effect of using a disease-specific measure of HRQoL to calculate

QALYs rather than EQ-5D. The effect of the decision to prioritise hospital data over patient-recorded data was also explored with an analysis using only resource use data recorded by patients. The effect of costing hospital stays as either long or short stays based on Hospital Episode Statistics (HES) classifications, rather than using a cost per day, was also explored. Finally, the effect of using the same dose (250-mg) tablets to calculate treatment costs for all patients in the levofloxacin arm of the trial was explored in a sensitivity analysis that instead calculated treatment costs using 500-mg levofloxacin tablets for patients who took 250 mg or 500 mg (the same costing method as in the base case was used for patients who took 125 mg of levofloxacin). ICERs from each of the scenarios were compared with the main trial results to identify areas of uncertainty.

For the 12-month analysis, the sensitivity of results to the choice of prediction model employed was also evaluated.

Uncertainty analysis

The level of sampling uncertainty around the ICER was determined using a non-parametric bootstrap to generate 10,000 estimates of incremental costs and benefits. The bootstrapped estimates were plotted on the cost-effectiveness plane to illustrate the uncertainty surrounding the cost-effectiveness estimates.[53] Net monetary benefit (NMB) was also calculated for each of the bootstrapped estimates. NMB combines cost-effectiveness and willingness to pay (WTP) to give an explicit monetary valuation of the health outcome. It is calculated by rearranging the ICER and incorporating the WTP per QALY threshold value, such that NMB is derived for each patient as:

$$\text{NMB} = (\lambda \times \text{QALYs}) - \text{costs}, \tag{3}$$

where λ is the value a decision-maker would be willing to pay per incremental QALY gained. For any given threshold value (λ), treatments with an average incremental NMB of > 0 should be adopted. The expected NMB was used to estimate the probability that antibiotic prophylaxis is cost-effective given a range of threshold values ($\lambda = £1000$ to $\lambda = £100,000$) that were plotted on the cost-effectiveness acceptability curve (CEAC).[54] The CEAC illustrates the probability that antibiotic prophylaxis is cost-effective compared with placebo when used alongside antimyeloma treatment as a function of the WTP threshold (λ). It is constructed using 10,000 bootstrapped samples from the original data and plotting the proportion of times each treatment represents the maximum average net benefit for a range of WTP thresholds (λ). The cost-effectiveness frontier was also plotted to show the intervention that provides the highest net benefit for a given threshold.

Value-of-information analysis

Value-of-information analysis was conducted to estimate the potential gains from the elimination of uncertainty that could result from conducting additional research.[50] As decisions must be made based on the information that is currently available, and as such information may be imperfect, there remains an element of uncertainty and a chance that the wrong decision will be made. In the event of a 'wrong' decision, costs will be incurred in the form of health benefit and cost of resources forgone. The expected value of perfect information (EVPI) is derived from the expected costs associated with the uncertainty. The EVPI was calculated using the bootstrapped sample to calculate the average net benefit loss as a result of the 'wrong' decision. EVPI was calculated as follows:

$$\text{EVPI} = E_\theta \max_j \text{NB}(j, \theta) - \max_j E_\theta \text{NB}(j, \theta), \tag{4}$$

where $E_\theta \max_j \text{NB}(j,\theta)$ is the expected net benefit with perfect information and $\max_j E_\theta \text{NB}(j,\theta)$ is the expected net benefit with current information. The expected net benefit with perfect information is calculated as the mean value of NMB when the intervention with the higher NMB is chosen for each simulation. The expected net benefit with current information is calculated as the mean value of NMB when the intervention with the higher expected net benefit is chosen across all simulations.[55]

There were 5540 new cases of myeloma in 2015 in the UK given an age-standardised incidence rate of 9.6 per 100,000 population.[1] It was assumed that the decision is relevant for a period of 10 years, after which time it is reasonable to assume that the treatment pathway may have changed (i.e. alternative therapies becoming available). The EVPI is presented for this population with myeloma in the UK over a range of cost-effectiveness thresholds. A discount rate of 3.5% was used to discount the future value of additional research to the present value.[39] If additional research that removes uncertainty can be conducted at an expected cost lower than the EVPI, then such research may be warranted.

Results

Sample

Of the 977 patients recruited to the trial, complete resource use and EQ-5D results for all follow-ups were available for 511 patients.

Resource use and costs

Table 30 shows the average resource use of all patients in each treatment arm who returned at least one resource use questionnaire over the 16-week duration of the trial (levofloxacin, $n = 469$; placebo, $n = 461$). *Table 31* also gives a more detailed breakdown of hospital admissions from the available hospital data. Average health-care costs over the trial period are presented in *Table 32*. The mean total costs of community health and social services were £224.87 [standard deviation (SD) £605.66] for the levofloxacin group and £190.13 (SD £486.41) for the placebo group. The mean total costs for hospital and residential care services were £3620.60 (SD £4579.35) for the levofloxacin group and £3255.17 (SD £4167.70) for the placebo group. For relevant unit costs, see *Table 46*. For further breakdown of resource use and costs, see *Tables 47* and *48*.

Independent-sample *t*-tests were undertaken to explore differences in mean total NHS costs associated with the treatment arms. Although the difference in total NHS costs appears considerable, the difference was not significant at the 5% level ($p = 0.053$).

Quality-of-life data

Mean (SD) EQ-5D scores for each treatment arm at each time point are presented in *Table 33*. When patients died during the trial, the EQ-5D score was recorded as 0 from the date of death. EQ-5D scores increase throughout the trial period in both treatment arms. This increase is slightly larger in the levofloxacin group. Baseline EQ-5D scores were very similar and independent-sample *t*-tests indicated that there was no statistically significant difference in EQ-5D scores at baseline ($p = 0.88$). The primary analysis uses an

Missing data

A total of 521 patients had complete EQ-5D scores across all time points. The remaining 456 patients had EQ-5D scores missing for at least one of the time periods. There were 112 (11%) missing EQ-5D scores at baseline, which were imputed independently of treatment allocation. A total of 934 (24%) EQ-5D scores were missing across the remaining follow-ups (weeks 4–16) and were imputed for the cost-effectiveness analysis. Of those scores that were missing, 71 (2%) were missing as a result of partially completed EQ-5D forms and the remaining were missing in all elements of the EQ-5D. A total of 704 patients completed resource use questionnaires for all follow-ups. The remaining 273 had missing resource use for at least one of the time periods. At the first follow-up in week 4, 887 (91%) patients completed resource use questionnaires. The completion rate dropped over the duration of the trial to 84% completed at week 8, 80% completed at week 12 and 76% completed at week 16.

Cost-effectiveness results

Cost-effectiveness results are presented in *Table 35*, which shows the costs and QALYs gained for each treatment arm, the incremental costs and QALYs, and the resulting ICER. The levofloxacin group had the highest QALYs gained over the trial period. The mean total cost was also highest for the levofloxacin group.

The results suggest that the use of prophylactic levofloxacin would not be cost-effective compared with placebo. This is as a result of smaller QALY gains and higher costs in the levofloxacin arm than in the placebo arm. An ICER value of £231,377.42 per QALY gain is yielded, which is well above the NICE cost per QALY threshold.

Bootstrapped estimates of the incremental costs and incremental effects are plotted on the cost-effectiveness plane in *Figure 7*. This shows the joint distribution of incremental costs and incremental effects in the cost-effectiveness plane for levofloxacin compared with placebo. Most of the points in the

TABLE 35 Cost-effectiveness results

	Mean (SD)	Incremental	Mean (SD)	Incremental	
Placebo	3272.19 (4173.23)		0.1818 (0.006)		
Levofloxacin	3871.45 (4622.02)	599.26	0.1845 (0.006)	0.0026	231,377.42

FIGURE 7 The cost-effectiveness plane: levofloxacin vs. placebo.

cloud lie above the cost-effectiveness threshold line, indicating that the use of levofloxacin is unlikely to be a cost-effective use of resources. Although 98.2% of the iterations fall in the north-east quadrant (more costly, more beneficial), only 1.8% fall in the south-east quadrant (less costly, more beneficial).

Net monetary benefit

The NMB for each treatment arm, calculated from the bootstrapped estimates of costs and QALYs, is presented in *Table 36*. Given the decision rule, the NMB results indicate that the use of prophylactic levofloxacin is not a cost-effective use of resources because the expected value of NMB is negative.

The probability that the treatments are cost-effective is presented on the CEAC shown in *Figure 8*. This shows that the use of prophylactic levofloxacin is very unlikely to be a cost-effective use of resources even at high cost-effectiveness threshold values.

Sensitivity analysis

The cost-effectiveness results for each scenario explored in the sensitivity analysis are presented in *Table 37*.

Given that the base-case analysis was conducted using imputed data, a sensitivity analysis that used only complete cases was conducted. In addition, sensitivity analyses were conducted to explore the effect of adjusting for baseline differences by repeating the analysis without the baseline adjustment, and to explore the effect of the decision to give precedence to hospital data by using patient-reported hospital admission data instead of the hospital-provided data. The effect of using a condition-specific measure of HRQoL compared with a generic measure was also explored with a sensitivity analysis using the EORTC QLQ-C30 instead of the EQ-5D. A sensitivity analysis was also conducted to explore the effect of costing hospital stays as either long or short stays based on HES classifications, rather than using a cost per day (see *Table 46* for relevant unit costs). A final sensitivity analysis was conducted in which treatment costs were calculated using 500-mg levofloxacin tablets for patients who took 250 mg or 500 mg, rather than calculating the cost of treatment using 250-mg tablets for all patients. In each case, the results of the sensitivity analyses support the results of the base-case analysis and indicate that the use of prophylactic levofloxacin is not a cost-effective use of resources.

Secondary analysis

A secondary analysis to explore the cost per febrile episode avoided was also conducted. In line with the primary outcome of the trial, this analysis was conducted over a 12-week time horizon. There were no missing febrile episode data and cost data were imputed using multiple imputation as in the primary health economic analysis. Cost-effectiveness results from the secondary analysis are presented in *Table 38*. This shows that the additional cost per febrile episode avoided was £4021.26. This amounts to a mean additional cost of £8.15 per patient treated (calculated as the difference in mean cost per patient between the treatment arms/incremental febrile episodes avoided).

Explicit predefined reference threshold values to allow interpretation of the cost per febrile episode avoided are not available. However, the cost of treating a febrile episode may be used as a yardstick for interpretive purposes. A generalised linear model (family: gamma; link: identity) was fitted to the trial cost data to estimate the cost of an infection. This produced an estimate of the cost of an infection of £1805.87 (standard error 180.22). As the cost of treating an infection is lower than the cost of preventing a febrile episode, it may be concluded that the use of levofloxacin for prevention is not a cost-effective use of resources.

	Incurred (12 weeks)	Incremental	Total number	Incremental avoided	
Placebo	581,503.40		149		
Levofloxacin	722,247.50	140,744.06	114	35	4021.26

Secondary analysis: sensitivity analysis

The cost-effectiveness results for each scenario explored as sensitivity analyses are presented in *Table 39*. Sensitivity analyses were conducted to explore the effect of uncertainty in the estimates of costs. As in the primary analysis, the effect of the decision to give precedence to hospital data was explored in a sensitivity analysis using patient-reported hospital admission data instead. Scenarios considering a reduction in overall costs (−20%) and an increase in overall costs (+20%) were also explored. In each case, the results of the sensitivity analyses support the results of the base-case analysis and indicate that, when compared with an estimated cost per infection of £1806, the use of levofloxacin does not appear to be a cost-effective use of resources.

Value-of-information analysis

The population EVPI at the NICE cost-effectiveness threshold value of £20,000 per QALY gained is £99,131. The population EVPI for other values of the cost-effectiveness threshold is plotted in *Figure 9*.

TABLE 39 Sensitivity analysis: cost per febrile episode avoided

Discussion

Principal findings

The trial-based cost-effectiveness analysis indicated that the use of prophylactic levofloxacin alongside antimyeloma treatment was not a cost-effective use of NHS resources compared with placebo.

Both treatment arms showed an increase in EQ-5D score over the trial period but, although levofloxacin was associated with slightly higher total QALY gains, the difference in QALYs was very small. This may, in part, be explained by the fact that benefits were measured only over the trial period of 16 weeks and that any longer-term benefits were not considered. In terms of costs, the levofloxacin arm was found to be the most costly treatment. This was driven by greater resource use in the levofloxacin arm, both in terms of hospitalisations and the use of community health and social services. Consequently, the principal finding that the use of prophylactic levofloxacin would not be a cost-effective use of resources is driven by the (statistically significant) difference in costs.

Base-case cost-effectiveness results were not sensitive to alternative assumptions explored in the sensitivity analyses. The secondary analysis found that the cost per febrile episode avoided in the levofloxacin arm was £8849.31. In the absence of a predefined decision rule for outcomes measures in natural units, the value judgement on whether or not this presents a good use of resources is left to the decision-maker.

An estimate of the value of perfect information suggested that further research to remove uncertainty and enable more robust economic decisions to be made would be worth £99,131. If additional research can be conducted at an expected cost lower than this value, then such research would be warranted to reduce uncertainty.

Strengths and weaknesses of the economic analysis

The main strength of this analysis lies in the randomised controlled design of the trial. This enabled the collection of high-quality data that were subsequently used in this analysis to conduct the 16-week within-trial analysis.

However, the relatively short duration of follow-up has made consideration of longer-term outcomes difficult. This has partly been addressed by conducting an extrapolated analysis over a 12-month time horizon; however, the use of more robust methods to consider a longer follow-up would be beneficial as part of any future research.

Meaning of the trial

Although fewer febrile episodes and deaths were experienced in the levofloxacin arm of the trial, this does not translate into the use of prophylactic levofloxacin being a cost-effective use of resources. This is driven by higher costs in the levofloxacin arm as a result of high levels of resource use in terms of both hospitalisations and the use of community health and social services that are maintained despite the reduction in infections. Consequently, the higher costs in the levofloxacin arm combined with only very small gains in QALYs indicate that the use of prophylactic levofloxacin would not be a cost-effective treatment option alongside antimyeloma treatment.

Unanswered questions and further research

Although the analysis conducted here provides useful insights into the costs and effects over the trial period of 16 weeks, further research is required to provide more robust evidence on the cost-effectiveness over a longer time horizon. This will be particularly relevant if the benefits of prophylactic levofloxacin are maintained or develop in the long term. More research is needed to investigate whether or not the cost for avoided febrile episode is cost-effective.[56]

Chapter 5 Discussion

Interpretation

The trial indicated that prophylactic levofloxacin caused a significant reduction in febrile episodes and deaths during the 12-week treatment period (log-rank = 9.78; $p = 0.002$). The largest benefit was observed within 4–8 weeks. Levofloxacin also reduced the number of other (non-febrile) infectious episodes (p-trend = 0.06). The data gathered on these 'other infections' are of particular interest because these data have not, to our knowledge, been previously collected on such a large scale. Our data show that these 'other infections' are a substantial burden for both patients and the health-care system. They were more frequent than febrile episodes (323 other infections vs. 264 febrile episodes). Again, the benefit of prophylaxis in these 'other infections' became apparent during the 4- to 8-week period and continued up to 12 weeks. The body site experiencing the greatest reduction in infections was the urinary tract, probably because levofloxacin is broadly effective against Gram-negative organisms. Upper respiratory tract infections are frequently caused by viruses and, therefore, would be unaffected by levofloxacin.

Information on infections was collected only up to 12 weeks but longer-term survival data were collected up to 12 months. During months 3–6, patients were not on prophylaxis and yet the survival benefit continued for those who had taken levofloxacin. If levofloxacin had prevented death in those patients destined to respond to antimyeloma treatment and subsequently survive beyond 12 months, the survival benefit might have been expected to continue. A possible interpretation of our finding that the survival curves came together by 6 months is that levofloxacin may reduce or delay the risk of death in patients with poorly responsive or refractory disease. Therefore, the cause of death was analysed in the 116 deaths reported during the 12-month trial period. There were fewer deaths attributed to infection in the levofloxacin arm (three patients) than in the placebo arm (eight patients) during the 12-week treatment period, but more in the levofloxacin arm (19 patients) than in the placebo arm (12 patients) post 12 weeks. These data support our possible interpretation outlined above. Although levofloxacin may have reduced the number of deaths in the first 12 weeks from 22 to 8, there were a further 86 deaths in the next 40 weeks from many causes and the reversal of levofloxacin survival advantage may have been influenced by the volume of the later deaths.

There was little benefit from levofloxacin until after the first 4 weeks, and this time delay in benefit from prophylaxis in reducing febrile episodes and other infections is intriguing. The response to treatment of an established infection with antibiotics is expected within 48 hours. This observed delay in benefit from prophylaxis may suggest that some form of biological process needs to take place before the benefit is realised. One suggestion may be that a change in the patient's immune response or microbiome may be necessary before the benefit of prophylaxis is established. The theory that a biological process may take place in the patient before the benefit of prophylaxis becomes apparent may also be supported by the observation that the survival curves remained separated for months 3–6. It is possible that the benefit of levofloxacin prophylaxis may continue to reduce infections for a period after withdrawing levofloxacin, but this was not measured in the trial.

There was no significant increase in HCAIs in patients on levofloxacin during the 16 weeks of the trial, disproving the theory that the use of prophylactic levofloxacin may trigger an excess of HCAIs. In addition, despite prospectively looking for colonisation with resistant organisms, there were fewer episodes of colonisation noted in the levofloxacin arm. However, it is possible that a longer period of levofloxacin prophylaxis may induce colonisation or infection with HACIs. There is a need to better understand the reasons for the risks of colonisation with resistant organisms and infections in the first 4 weeks of levofloxacin prophylaxis. There is also a need to explore the effects of a longer duration of levofloxacin prophylaxis.

A total of 597 SAEs were reported (308 in the levofloxacin group and 289 in the placebo group), with most reported as unlikely to be related to or unrelated to the study drug (537/597 events, 90%) and a majority reported to be attributable to hospitalisation or prolongation of existing hospitalisation (462/597 events, 77%). Toxicity reported to be related to levofloxacin (38 episodes) compared with placebo (22 episodes) had a tendency to manifest as gastrointestinal disorders, rash, psychiatric disorders and musculoskeletal/connective tissue disorders, but these were very rare events.

The health economic analysis showed a slight increase in QALYs over 16 weeks for levofloxacin prophylaxis, but this was associated with higher health-care costs. Despite the reduction in febrile episodes and deaths in the patients taking prophylactic levofloxacin, the 16-week cost-effectiveness analysis indicated that prophylactic levofloxacin would not be a cost-effective use of NHS resources. This result was driven by higher use of health-care resources in the levofloxacin arm and only very small gains in QALYs. Consequently, the aforementioned reduction in febrile episodes and deaths did not translate into gains in QALYs that were sufficient to outweigh the additional costs. This result was robust to sensitivity analyses. As the benefit of levofloxacin prophylaxis in reducing infections and death became most apparent after 4 weeks, it would be useful to perform the analysis over the period of 4–16 weeks. This analysis is planned for the future. In addition, the analysis of 12-month data is ongoing. More research is needed to investigate whether or not the cost for avoided febrile episode is cost-effective.[56]

Generalisability

Strengths of the study

This was a large randomised, double-blind, placebo-controlled trial for the intervention, with broad entry criteria, and patients with poor performance status were not excluded. Patients could be on any antimyeloma treatment regimen; hence, data were collected prospectively in a real-life situation. All suspected infectious episodes were captured, with the only definition being that patients were given an anti-infective treatment by a health-care professional. These data were the most comprehensive yet recorded for newly diagnosed multiple myeloma patients. A large number of patient and treatment data have been recorded, which allowed the analysis of secondary outcomes as prespecified in the protocol. The longer-term secondary analyses, such as detailed survival analysis and analysis of cost-effectiveness up 12 months and QoL, are ongoing.

Limitations of the study

Despite the study having broad entry criteria, the patient population recruited into the study was healthier than expected, with a median age of 67 years and only 7% of patients of performance status 3 or 4. The 3-month overall survival of patients in our study was in excess of 95%. However, population data show that the median age of myeloma patients at diagnosis is 71 years and the 3-month overall survival is 83%.[57] Therefore, the study was not fully representative of the patient population presenting with multiple myeloma. There was a concern raised by some investigators at the start of the trial that the prophylactic use of antibiotics may trigger HCAIs and, as a consequence, that there may have been a degree of selection bias to randomise fitter patients into the trial. Despite refining the protocol to include patients with impaired renal function, more patients than expected had eGFR values within the > 50 ml/minute/1.73 m^2 range, which may be a reflection of over selection of fewer patients with renal impairment.

Patients had to be willing to provide stool samples and nasal swabs throughout the study as well as to complete the daily diary with data on temperature, patient-reported outcomes and QoL. Screening logs were collected and the main reason for not entering the trial was the unwillingness to provide samples and complete daily diaries. There was a protocol amendment early in the study to allow patients to enter the study within 14 days of starting antimyeloma treatments rather than 7 days, as initially stipulated. It may be that recruitment to a supportive care trial needs to accommodate patient emotions around receiving a diagnosis of myeloma and starting antimyeloma treatment before supportive care interventions can be considered.

The recruitment of a relatively healthy patient population to this study has several implications. The benefit of levofloxacin prophylaxis may be even more pronounced in the general myeloma population than the study demonstrated. In addition, if levofloxacin prophylaxis reduces infection and death in some poor performance status patients who have biologically responsive disease but are at risk of early death because of frailty, there could be a prolonged survival benefit for these patients. Our study may not have been able to demonstrate this because it was a selected patient population.

Levofloxacin prophylaxis was given for only 12 weeks. As the benefit in favour of levofloxacin was still evident at this time point, it is possible that there may be a benefit to continuing prophylaxis for longer.

It is important to note that a relatively low *C. difficile* carriage at baseline was found for patients on the TEAMM trial (0.7% compared with an expected 10% in hospital patients and 1% in the general population), which may be a reflection of the new NHS policies to minimise infections in hospital or the fact that many of these patients are mainly outpatients.

Overall evidence

This study supports the use of levofloxacin as prophylaxis for myeloma patients undergoing antimyeloma treatment. A small study of prophylactic co-trimoxazole in early myeloma showed a reduction in bacterial infections but was too small to detect reduced mortality and 25% of patients were unable to tolerate the drug.[18] Two large studies[22–24,58] confirmed the efficacy of prophylactic levofloxacin in preventing bacterial infection in neutropenia, and subsequent meta-analyses showed superiority of fluoroquinolone antibiotics over other classes of antibiotic.

Overall conclusions

In the authors' opinion, this study supports the use of prophylactic levofloxacin for patients undergoing antimyeloma treatment. This is the largest study in the literature assessing the use of levofloxacin to reduce febrile episodes and other infections for myeloma patients. Most patients in the trial were fitter then expected with a lower carriage rate of *C. difficile*.

There was no difference for new acquisitions of or invasive infections by *C. difficile*, MRSA and ESBL Gram-negative organisms when assessed up to 16 weeks.

Despite being clinically effective, levofloxacin in prophylaxis is not a cost-effective health-care programme from the NHS standpoint. However, this result is focused only on incremental QALYs gained, which are usually negligible when measured for such a short period of time (16 weeks). More research is needed to investigate whether or not the cost for avoided febrile episode is cost-effective.

Further research

Laboratory investigation of immunity, inflammation and disease activity on stored samples (funded by the TEAMM NIHR EME programme grant reference number 14/24/04) will provide insights into the triad of (1) myeloma disease activity, (2) immune competence and (3) infections and HCAIs to stratify patients for risk of infection, to guide use of prophylactic antibiotics and to improve response to antimyeloma therapies.

Further research to establish the optimal duration of prophylactic antibiotics for these patients is needed. There may be a benefit to treat for the whole duration of antimyeloma treatment in order to give maximum protection for these patients. In addition, the use of Septrin gave additional benefit to levofloxicin. This needs to be investigated within a future clinical trial.

Health economists

David Meads, Bryony Dawkins and Claire T Hulme.

Patient and public involvement

Eric Low was a co-applicant, member of the Trial Management Committee and Trial Steering Committee and, together with colleagues from Myeloma UK, commented on the drafting of the protocol and PIS as well as the main report. We would also like to acknowledge all of the 977 trial participants, especially those who returned their patient diaries and QoL booklets.

The local NHS teams

The TEAMM team would like to thank the NHS trusts and participating PIs and their colleagues for recruiting and monitoring trial participants. These include [in alphabetical order of participating hospitals preceded by the local PI(s)] Feargal McNicholl of Altnagelvin Hospital; Philip Windrum of Antrim Hospital; Joanne Howard and Parag Jasani of Basildon University Hospital; Sylwia Simpson of Basingstoke and North Hampshire Hospital; Paul Kettle and Oonagh Sheehy of Belfast City Hospital; Adrian Williams of Bradford Royal Infirmary; Vijoy Chowdhury of Broomfield Hospital; Sylvia Feyler, Kate Rothwell and Srivasavi Dukka of Calderdale Royal Hospital; Haz Sayala and David Allsup of Castle Hill Hospital; Sally Chown of Cheltenham General Hospital; Robert Cutting, Emma Welch and Peter Toth of Chesterfield Royal Hospital; Michael Hamblin and Gavin Campbell of Colchester General Hospital; Salaheddin Tueger of Countess of Chester Hospital; Aurangzeb Razzak and Kamaraj Karunanithi of County Hospital stafford; Kathryn Boyd of Craigavon Area Hospital; Anil Kamat and Tariq Shafi of Darent Valley Hospital; John Ashcroft of Dewsbury Hospital; Susan Levison-Keating of Diana, Princess of Wales Hospital; Akeel Moosa of Dorset County Hospital; Richard Kaczmarski and Taku Sugai of Ealing Hospital; Alistair Whiteway of Frenchay Hospital; Jagadeesh Gandla and Jhansi Muddana of George Eliot Hospital; Earnest Heartin of Glan Clwyd Hospital; Sally Chown of Gloucestershire Royal Hospital; Bhuvan Kishore of Good Hope Hospital; Sandor Lueff, Kandeepan Saravanamuttu, Caroline Harvey and Charlotte Kallmeyer of Grantham Hospital; Norbert Blesing of Great Western Hospital; Matthew Streetly of Guy's and St Thomas' Hospital; Guy Pratt and Bhuvan Kishore of Heartlands Hospital; Lisa Robinson of Hereford County Hospital; Richard Kaczmarski of Hillingdon Hospital; Sylvia Feyler, Kate Rothwell and Srivasavi Dukka of Huddersfield Royal Infirmary; Mark Kwan of Kettering General Hospital; Steve Schey and Stella Bowcock of King's College Hospital; Rowena Faulkner and Tim Moorby of King's Mill Hospital; Samir Zebari of Kingston Hospital; Claire Chapman and Mamta Garg of Leicester Royal Infirmary; Kamaraj Karunanithi of Leighton Hospital; Sandor Lueff, Kandeepan Saravanamuttu, Caroline Harvey and Charlotte Kallmeyer of Lincoln County Hospital; John Hudson of Macclesfield District General Hospital; Simon Gibbs, Eleni Tholouli and Alberto Rocci of Manchester Royal Infirmary; Vivienne Andrews, Vijayavalli Dhanapal and Sarah Arnott of Medway Maritime Hospital; Moez Dungarwalla of Milton Keynes Hospital; Nilima Parry-Jones of Nevill Hall Hospital; Abraham Jacobs and Supratik Basu of New Cross Hospital; Claudius Rudin of North Devon District Hospital; Neil Rabin of North Middlesex University Hospital; Jane Parker of Northampton General Hospital; Charalampia Kyriakou of Northwick Park Hospital; Sandor Lueff, Kandeepan Saravanamuttu, Caroline Harvey and Charlotte Kallmeyer of Pilgrim Hospital; John Ashcroft of Pinderfields Hospital; John Ashcroft of Pontefract Hospital; Rebecca Maddams and Fergus Jack of Poole Hospital; Stella Bowcock of Princess Royal University Hospital; Helen Dignum and Edward Belsham of Queen Alexandra Hospital; Mark Cook of Queen Elizabeth Hospital; Ramaprabhahari Sathesh-Kumar and Martin Lewis of Queen Elizabeth Hospital, King's Lynn; Tullie Yeghen of Queen Elizabeth Hospital, Woolwich; Humayun Ahmad of Queen's Hospital, Burton upon Trent; Biju Krishnan and Sandra Hassan of Queen's Hospital, Romford; Karthick Ramasamy and Henri Grech of Royal Berkshire; Rachel Hall of Royal Bournemouth Hospital; Claudius Rudin of Royal Devon & Exeter Hospital; Helen Jackson of Royal Gwent Hospital; Yousef Ezaydi of Royal Hallamshire Hospital; Katharine Lowndes of Royal Hampshire County Hospital; Stephen Hawkins of Royal Liverpool University Hospital; Kamaraj Karunanithi

Other acknowledgements

Contributions of authors

Mark T Drayson (Chief Investigator) was responsible for identifying the research question and writing the trial protocol, the central laboratory analysis and the review of the blood and urine samples.

Stella Bowcock (Co-Chief Investigator) was responsible for identifying the research question and writing the trial protocol.

Tim Planche (Microbiology Advisor) was responsible for identifying the research question and writing the trial protocol, provided expert microbiology advice and performed the analysis on the stool samples and nasal swabs.

Gulnaz Iqbal (Trial Statistician) was responsible for identifying the research question and writing the trial protocol, and carried out the statistical analysis and interpreted the results.

Guy Pratt (Haematologist) was responsible for identifying the research question and writing the trial protocol.

Kwee Yong (Haematologist) was responsible for identifying the research question and writing the trial protocol.

Jill Wood (Trial Co-ordinator) managed the co-ordination and administration of the trial.

Kerry Raynes (Trial Co-ordinator) managed the co-ordination and administration of the trial.

Helen Higgins (Senior Project Manager) managed the co-ordination and administration of the trial.

Bryony Dawkins (Health Economics) conducted the health economic analysis.

Data-sharing statement

All data requests should be submitted to the corresponding author for consideration. Access to anonymised data may be granted following review.

Patient data

This work uses data provided by patients and collected by the NHS as part of their care and support. Using patient data is vital to improve health and care for everyone. There is huge potential to make better use of information from people's patient records, to understand more about disease, develop new treatments, monitor safety, and plan NHS services. Patient data should be kept safe and secure, to protect everyone's privacy, and it's important that there are safeguards to make sure that it is stored and used responsibly. Everyone should be able to find out about how patient data are used. #datasaveslives You can find out more about the background to this citation here: https://understandingpatientdata.org.uk/data-citation.

Appendix 1 Additional recruitment details

*T*able 40 lists the sites that did not want to participate in the trial and their reasons for not participating.

TABLE 40 Sites not wishing to participate

Site	Reasons for not participating
University College London Hospital	*C. difficile* risk
Ysbyty Gwynedd	Withdrew because of a MHRA safety alert for levofloxacin and acute liver injury
Peterborough City Hospital	Decided against participating after reading protocol: no reason given
Harrogate District Hospital	*C. difficile* risk
Maidstone Hospital	*C. difficile* risk
Scunthorpe General Hospital	No response
Luton and Dunstable Hospital	Capacity: may review again
East Surrey & Crawley Hospitals	*C. difficile* risk
Frimley Park Hospital	*C. difficile* risk
Ashford and St Peter's Hospitals	*C. difficile* risk
Chelsea and Westminster Hospital	Postage cost
MHRA, Medicines and Healthcare products Regulatory Agency.	

Table 41 lists the numbers of patients screened and randomised at each site.

TABLE 41 Numbers of patients screened and randomised at each site

| | Patients (*n*) | |
Site	Screened	Randomised
Altnagelvin Hospital	24	11
Antrim Hospital	20	4
Basildon University Hospital	28	5
Basingstoke and North Hampshire Hospital	6	3
Bradford Royal Infirmary	44	8
Broomfield Hospital (Chelmsford)	17	8
Calderdale Royal and Huddersfield Royal Infirmary	32	9
Castle Hill Hospital (Cottingham)	34	17
Chesterfield Royal Hospital	33	13
Colchester General Hospital	71	31
County Hospital	–	10
Craigavon Area Hospital	17	6
Darent Valley Hospital (Dartford)	111	23
Diana, Princess Of Wales Hospital (Grimsby)	5	2

continued

TABLE 41 Numbers of patients screened and randomised at each site (*continued*)

Site	Patients (*n*)	
	Screened	Randomised
Dorset County Hospital (Dorchester)	10	2
Ealing Hospital (Southall)	25	12
Frenchay Hospital (Bristol)	–	3
George Eliot Hospital (Nuneaton)	16	6
Glan Clwd Hospital (Rhyl)	–	1
Glangwili General Hospital	15	10
Gloucestershire Royal Hospital	22	5
Good Hope Hospital	–	6
Grantham and District Hospital	–	2
Great Western Hospital	28	13
Guy's and St Thomas' Hospital	20	17
Heartlands Hospital	36	21
Hereford County Hospital	16	7
Hillingdon Hospital	4	2
Kettering General Hospital	5	2
King's College Hospital (Denmark Hill, London)	–	4
King's Mill Hospital (Sutton-in-Ashfield)	–	25
Kingston Hospital (Kingston upon Thames)	17	4
Leicester Royal Infirmary	–	7
Leighton Hospital (Crewe)	9	3
Lincoln County Hospital	28	11
Macclesfield District General Hospital	10	1
Manchester Royal Infirmary	–	12
Medway Maritime Hospital (Gillingham)	35	26
Mid Yorkshire Hospitals	21	6
Milton Keynes Hospital	18	7
New Cross Hospital (Wolverhampton)	–	9
North Bristol Hospital	4	0
North Devon District Hospital	5	0
North Middlesex University Hospital Trust (London)	15	10
Northampton General Hospital	53	19
Northwick Park Hospital (Harrow)	43	11
Pilgrim Hospital (Boston)	–	7
Poole Hospital	–	2
Princess Royal University Hospital (Orpington)	42	31
Queen Alexandra Hospital (Portsmouth)	123	51

Site	Patients (*n*) Screened	Randomised
Wexham Park Hospital (Slough)	11	5
Whipps Cross University Hospital (London)	7	4
Withybush General Hospital (Haverfordwest)	6	3
Wrexham Maelor Hospital	36	18
Wycombe Hospital (High Wycombe)	23	10
Wythenshawe Hospital (Manchester)	19	11
Total	2183	977

The number of reasons for screening failures are reported in *Table 42*.

TABLE 42 Reasons for screening failure

Reason for screening failure	*n*	%
Declined, no reason given	278	23
Declined, too much going on	88	7
Not eligible/out of time window	290	24
Clinical decision	101	8
Location (e.g. moving to a new hospital)	36	3
Medication (e.g. did not want to take any more tablets or did not want to take antibiotics when did not have an infection, etc.)	49	4
Did not want to participate in a clinical trial/already on another clinical trial	79	6.5
Inability to consent (e.g. language barrier/confusion)	44	4
Did not want to/could not take samples	21	2
Died	9	1
Not known	211	17.5
Total	1206	100

Appendix 3 Health economic tables

TABLE 47 Unit costs

Resource item	Unit cost (£)	Source	Details
Trial medication			
Levofloxacin 250 mg	11.57 (per 10-tablet pack)	BNF 2017	Normal dose: two tablets per day
			Moderate renal failure: one tablet per day
			Severe renal failure: half tablet per day
Levofloxacin 500 mg	11.40 (per 10-tablet pack)	BNF 2017	
Community health and social services			
GP visit, surgery	36.00 (per visit)	PSSRU 2016, p. 145[45]	Per patient contact lasting 9.22 minutes, including direct care staff costs
GP visit, home	82.76 (per visit)	PSSRU 2016, p. 145[45]	Per patient contact lasting 9.22 minutes (plus an average 12-minute travel time) × £3.90/minute
Telephone GP	14.60	PSSRU 2016, p. 147[45]	Telephone triage, GP led, per clinician consultation lasting 4 minutes
District nurse visit	38.00 (per visit)	*NHS Reference Costs 2015 to 2016*[46]	District nurse, adult, face to face. CC: N02AF; SC: NURS
Practice nurse visit	12.14 (per visit)	PSSRU 2015, p. 174[43] PSSRU 2016, p. 143[45]	Per 15.5-minute consultation,[43] based on £43.00 per hour[45]
Home help or care worker visit	24.00 (per visit)	PSSRU 2016, p. 160[45]	Face-to-face 1-hour weekday session
Acupuncture	120	*NHS Reference Costs 2015 to 2016*[46]	General medicine: acupuncture for pain management CC: AB23Z; SC: 300
Telephone call with research/ specialist nurse	7.90	PSSRU 2016, p. 147[45]	Telephone triage, nurse led, per telephone consultation lasting 6.56 minutes
Chiropodist/podiatrist	32.00	PSSRU 2016, p. 135–7[45]	Chiropodist/podiatrist band 5, face to face, 1 hour
Specialist nurse	44.00	PSSRU 2016, p. 186–8[45]	Nurse specialist band 6, 1 hour
Counsellor	42.00	PSSRU 2016, p. 135–7[45]	Counsellor band 6, face to face, 1 hour
Day care	61.00	PSSRU 2016, p. 28[45]	Local authority provision day care per client attendance
Occupational therapist	32.00	PSSRU 2016, p. 135–7[45]	Occupational therapist band 5, face to face, 1 hour
Physiotherapy	32.00	PSSRU 2016, p. 135–7[45]	Physiotherapist band 5, face to face, 1 hour
Psychologist	52.00	PSSRU 2016, p. 135–7[45]	Clinical psychologist band 7, face to face, 1 hour

TABLE 47 Unit costs (*continued*)

Resource item	Unit cost (£)	Source	Details
Phlebotomy	61.00 (58.00 + 3.00)	*NHS Reference Costs 2015 to 2016*[46]	Phlebotomy DAPS08 and community nurse (1 hour)
		PSSRU 2015, p. 169[43]	
Palliative care nurse	136.00	*NHS Reference Costs 2015 to 2016*[46]	Medical specialist palliative care SD04A
Palliative care (non-medical)	69.00	*NHS Reference Costs 2015 to 2016*[46]	Non-medical specialist palliative care (other)
Telephone occupational therapist	18.00	*NHS Reference Costs 2015 to 2016*[46]	Occupational therapy, consultant led, not admitted, non-face to face, first
Social worker	55.00	PSSRU 2016, p. 156[45]	Social worker per hour of client-related work
Health visitor – postnatal	68.55	*NHS Reference Costs 2015 to 2016*[46]	Community midwife, post-natal visit N01P
Rapid response	79.00	PSSRU 2016, p. 101[45]	Per hour of service
Dentist (band 1)	51.75	PSSRU 2015, p. 181[43]	Dentist 15 minutes at £207.00 per patient hour
Dentist (band 2)	207.00	PSSRU 2015, p. 181[43]	Per patient hour
Hearing centre	63.00	*NHS Reference Costs 2015 to 2016*[46]	Audiometry or hearing assessment, ≥ 19 years CC: CA37A
Telephone 111	8.00	www.bbc.co.uk/news/health-22370621 (accessed 22 May 2017)	£7.50–8.50 per call
Blood test	15.14 (12.14 + 3.00)	*NHS Reference Costs 2015 to 2016*[46]	15.5-minute consultation with practice nurse (PSSRU 2015[43]) at £43.00 per hour plus blood test at £3.00
			Directly accessed pathology services – haematology CC: DAPS05
Hospital based or residential care services			
Hospital inpatient	298.41 (per day)	*NHS Reference Costs 2015 to 2016*[46]	Total Healthcare Resource Groups, average of all non-elective inpatient excess bed-days
Hospital critical/intensive care unit	521.00 (per day)	*NHS Reference Costs 2015 to 2016*[46]	Medical adult patients (unspecified speciality), adult critical care, zero organs supported, CC: XC07Z; SC: CCU03
Hospital short stay (hospital stay of 1 day)	478.00	*NHS Reference Costs 2015 to 2016*[46]	Non-elective short stay, malignant disorders of lymphatic or haematological systems
Hospital long stay (hospital stay of 2–5 days)	4850.00	*NHS Reference Costs 2015 to 2016*[46]	Non-elective long stay, malignant disorders of lymphatic or haematological systems
Hospital excess bed-days (cost per day after first 5 days)	338.00 (per day)	*NHS Reference Costs 2015 to 2016*[46]	Non-elective excess bed-days, malignant disorders of lymphatic or haematological systems
Hospital outpatient	135.00 (per visit)	PSSRU 2016, p. 95[45]	Weighted average of all outpatient attendances
A&E	137.74 (per visit)	*NHS Reference Costs 2015 to 2016*[46]	Emergency medicine, average unit costs of all emergency medicine attendances

TABLE 47 Unit costs (*continued*)

Resource item	Unit cost (£)	Source	Details
Residential home	90.00 (per day)	PSSRU 2016, p. 26[45]	Private sector residential home cost per permanent resident day
Paramedic	181.00	*NHS Reference Costs 2015 to 2016*[46]	Ambulance: see and treat or refer ASS01
Ambulance	236.00	*NHS Reference Costs 2015 to 2016*[46]	Ambulance: see, treat and convey ASS02
Dialysis	133.36	*NHS Reference Costs 2015 to 2016*[46]	Renal dialysis
Mammogram	30.00	*NHS Reference Costs 2015 to 2016*[46]	Direct access plain film
Chest radiograph	30.00	*NHS Reference Costs 2015 to 2016*[46]	Direct access plain film

A&E, accident and emergency; CC, currency code; SC, service code.

TABLE 48 Average resource use per patient in each treatment arm

Resource use, mean (SD)	Treatment arm							
	Levofloxacin				Placebo			
	Week 4	Week 8	Week 12	Week 16	Week 4	Week 8	Week 12	Week 16
Resources use data from resource use questionnaire only								
n valid (missing)	450 (39)	412 (77)	394 (95)	374 (115)	437 (51)	405 (83)	385 (103)	368 (120)
